

A HANDBOOK OF TROPICAL THERAPEUTICS

BY

R. N. CHOPRA

C.I.E., K.H.P., M.A., M.D. (CANTAB.), M.R.C.P. (LOND.)

Brevet-Colonel, Indian Medical Service

OFFG. DIRECTOR AND PROFESSOR OF PHARMACOLOGY AND THERAPEUTICS,
SCHOOL OF TROPICAL MEDICINE, CALCUTTA. PROFESSOR OF
PHARMACOLOGY, MEDICAL COLLEGE, CALCUTTA. SUPERINTENDENT
AND SENIOR PHYSICIAN, CARMICHAEL HOSPITAL FOR
TROPICAL DISEASES, CALCUTTA. FELLOW OF THE
CALCUTTA UNIVERSITY. FELLOW OF THE ASIATIC
SOCIETY OF BENGAL, ETC., ETC.

ART PRESS
20, BRITISH INDIAN STREET
CALCUTTA
1986

Printed and published by N. Mukherjee, B.A., at the Art Press
20, British Indian Street, Calcutta.

TO
MAJOR-GENERAL D. P. GOIL
K.H.P., M.B., CH.B., F.R.C.S.E., I.M.S.
AS A TOKEN OF ESTEEM

PREFACE

Since 1921 I have been engaged in teaching post-graduate students at the Calcutta School of Tropical Medicine and nearly a hundred medical practitioners from all parts of India and some from other tropical countries have annually passed through my hands. Medicine is taught in the Medical Schools and Colleges of India, chiefly from British and American text-books where the climatic and the morbid conditions are somewhat different from those in the tropics. It is not surprising, therefore, that the therapeutic methods described therein are not universally applicable in the environment under which the medical practitioners work in the tropics. It is not unusual to meet with disappointment in results and even untoward effects from the applications of such methods.

The importance of this fact has impressed me so greatly that I have thought it worth while to review the whole subject of therapeutics with due regard to the climatic conditions met with in the tropics generally and in India particularly. All the experience gained during the last fifteen years of intimate association with post-graduate teaching and treatment of patients in a well-equipped research hospital such as the Carmichael Hospital for Tropical Diseases has been collected and put together in book form so that the information is readily available. To encourage the rational use of drugs, the pharmacological actions of various remedies have been described before their therapeutic uses are discussed. The ætiology and pathology of disease have been mentioned briefly only in so far as it is necessary to make the treatment more comprehensible. These additions have made the book somewhat bulky.

I would like to emphasize that not only does this book include the results of my own personal experience, but that of many of my colleagues and co-workers in the Calcutta School of Tropical Medicine, who have very generously helped me in producing this volume. Had it not been for this co-operation and help the task would have been an impossible one. Every

section of the book has thus been thoroughly scrutinised by various experts on particular subjects, who have liberally contributed valuable criticisms and suggestions, which have been incorporated. In this connection I would like to put on record my very great indebtedness, my sense of gratitude and appreciation for the help which has been ungrudgingly given me by everyone concerned. Capt. C. L. Pasricha, I.M.S., Professor of Pathology and Bacteriology, was good enough to revise large sections of the part dealing with bacterial and virus diseases, and the skin diseases portion was entirely written by Dr. K. P. Banerji, and revised by Dr. L. M. Ghosh, from the notes of the late Lieut.-Col. H. W. Acton, C.I.E., I.M.S., who was a pioneer in tropical dermatology and who has greatly added to our knowledge of skin diseases in the tropics by his researches financed entirely by the Indian Research Fund Association. Dr. L. E. Napier and Dr. P. A. Maplestone, D.S.O., not only overhauled the sections dealing with their own subjects but went through the galley proofs and page proofs which involved an enormous amount of labour. To Dr. K. V. Krishnan, I am obliged for his help in writing the section on the Reticulo-endothelial system, and to Drs. J. P. Bose and Dharmendra for the sections on Diabetes and Asthma respectively. To Lt.-Col. R. Knowles, C.I.E., I.M.S., Professor of Protozoology, School of Tropical Medicine, Calcutta, Lt.-Col. J. Taylor, D.S.O., I.M.S., Director of the Central Research Institute, Kasauli, and Lt.-Col. E. H. Vere Hodge, I.M.S., Professor of Medicine, Medical College, Calcutta, I am grateful for criticisms and suggestions.

The book consists of six parts, as well as a dictionary of diseases and treatment, and appendices. Part I deals with general considerations in therapeutics and includes chapters on the action of drugs and conditions modifying drug action, modes of administration (including details of technique), chemotherapy (including drug resistance and the rôle of the reticulo-endothelial system), physiotherapy, diet and dietetics in the tropics, pyrexia, treatment of pain and insomnia and the use of tonics. This part may appear to be somewhat overloaded but the information given therein was considered to be essential. If

future editions are called for some of the sections from this part could perhaps be more appropriately transferred to the dictionary. Part II deals with the treatment of helminthic diseases and has been largely extracted from my book on this subject, written in conjunction with Dr. Asa C. Chandler, *Anthelmintics and their Uses in Medical and Veterinary Practice*, with the kind permission of the publishers, Messrs. Williams & Wilkins of Baltimore. A considerable amount of new information and the recent advances on the subject have been included. Part III deals with remedies used against protozoal diseases and is composed of four sections. The first section deals with remedies used against amœbiasis, the second against leishmaniasis and trypanosomiasis, the third against malaria and the fourth against spirochætal organisms. This is the most important part of the book from the point of view of tropical diseases and every effort has been made to discuss the relative value of different remedies in the treatment of protozoal diseases, as well as their modes of action, and to give a detailed account of the toxic effects produced and how to deal with them. Part IV discusses the treatment of bacterial and virus diseases which are of special interest in tropical climates. A large amount of space has been allotted to the general discussion on the uses of vaccines, sera and bacteriophage in therapeutics. Part V deals with the treatment of miscellaneous diseases met with in the tropics. The nutritional disorders, such as beriberi, epidemic dropsy, pellagra, etc., and metabolic disorders, including diabetes mellitus and obesity, have been dealt with. Special chapters have been given on tropical neurasthenia, treatment of the bites of snakes and other venomous animals and drug addiction. Every section up to here is followed by a list of the general literature and a selected bibliography which will be useful to those who want further details. Part VI deals with the treatment of skin diseases and is followed by a dictionary of diagnosis and treatment of the conditions met with in the tropics which cannot be strictly grouped under the heading of tropical diseases. The appendices give abstracts from journals, bringing certain sections up to date (end of 1935); there are also posological tables of drugs and preparations, notes regarding important non-official remedies, physiological

constants, tables of bacteria, metazoa and protozoa, and a large amount of other information required almost every day by the medical practitioner. The book is so designed that it will not only serve as a reference book for medical practitioners in the tropics but will also meet the requirements of senior students appearing in their final examinations. In spite of the great care that has been taken, the book possibly has many shortcomings and blemishes. I shall be very grateful for criticisms and suggestions so that in the next edition these defects can be removed.

I wish to acknowledge my indebtedness to the authors and publishers of the following books from which I have freely borrowed informations:—*A Manual of Pharmacology* by W. E. Dixon ; *A Manual of Pharmacology* by T. Sollmann ; *Parasitology* by Blacklock and Southwell ; *Tropical Medicine* by Rogers and Megaw ; *Recent Advances in Chemotherapy* by G. M. Findlay, and *Applied Pharmacology* by A. J. Clark.

I wish to place on record the valuable assistance I have received in writing this book from my former pupils and now co-workers in this institution, Drs. B. P. Mukherji, N. N. De, S. K. Ganguly and R. N. Chaudhuri who have worked incessantly, and M. D. Chakravartty on whom fell the task of abstracting from journals and looking up references. To Prof. S. Ghosh and Drs. J. C. Gupta, J. S. Chowhan, G. S. Chopra and B. Sen, I am very grateful for many valuable suggestions. The most difficult task of getting the book through the press has fallen on the shoulders of Dr. I. B. Bose who has worked ungrudgingly for over two years, sometimes under most difficult and trying circumstances.

To the Governing Body of the Indian Research Fund Association, Major-General C. A. Sprawson, C.I.E., K.H.P., I.M.S., Director-General, Indian Medical Service, and Col. A. J. H. Russell, C.B.E., K.H.P., I.M.S., I am very grateful for the generous grants they have given me to carry out researches in connection with indigenous drugs, drug addiction and the treatment of diseases in the tropics. But for the work done under the auspices of this Association the book would have lacked a good deal of originality.

To the publishers, the Art Press, I am very grateful for the efficient manner in which they have carried out the work. I am particularly grateful to Mr. N. Mukherjee, the proprietor, whom I cannot thank sufficiently for the patient and generous manner in which he has treated me.

R. N. CHOPRA

SCHOOL OF TROPICAL MEDICINE,
CALCUTTA,

CONTENTS

PART I

GENERAL CONSIDERATION IN THERAPY

	PAGE
CHAPTER I. ACTION OF DRUGS	1
The source and nature of drugs, 1; Action of drugs as basis of therapy, 2; Mode of action of drugs, 4; Selective or specific action, 5; Toxic effects, 7; Nature and results of drug action, 7; Absorption and distribution of drugs, 8; Absorption by the blood and lymph, 11; Sojourn of drugs in the blood, 12; Distribution of drugs in the body, 13; Changes in drugs during absorption, 13; Absorption, 14; Disintoxication by combination, 15; Excretion of drugs, 15; Passage into cerebro-spinal fluid, 15; Passage to foetus, 16.	
CHAPTER II. CONDITIONS MODIFYING THE ACTION OF DRUGS . . .	17
Cumulative action, 18; Dosage and effect, 18; Habit, 18; Sex, 19; Time of administration, 19; Idiosyncrasy and susceptibility, 20; Tolerance, 21; Effects of disease and pathological conditions, 22; Synergism and antagonism, 22.	
CHAPTER III. MODES OF ADMINISTRATION	25
Local application, 26; Oral and rectal administration, 28; Administration by injection, 32; Choice of drugs for injection, 37; Indications, 38; Advantages, disadvantages and contra-indications, 39; Reactions and dangers, 42; Intravenous therapy, 44; Substances that bring about a change in the blood condition, 44; Specific agents against protozoal organisms, 57; Agents used against bacterial organisms, 57; Intravenous administration of immunity producing agents, 62; Intravenous anaesthetics, 62; Agents that cause sclerosis of the veins, 63; Agents injected intravenously for diagnosis, 65.	
CHAPTER IV. ACIDOSIS AND ALKALOSIS	69
Acidosis in diabetes, 73; Acidosis in nephritis, 73; Acidosis in children, 74; Acidosis as a result of anaesthesia, 74; Reaction of blood in kala-azar, 75; Acidosis in malaria, 75; Acidosis in cholera, 75; Alkalosis, 75; Treatment of acidosis and alkalosis, 76.	
CHAPTER V. CHEMOTHERAPY	77
Theories of parasitotropism and organotropism, 81; Drug resistance, 84; in trypanosomiasis, 88; in spirochaetosis and syphilis, 90; Quinine resistance in malaria, 92; Reticulo-endothelial system 93; Phagocytosis of red cells, 98; of parasitic	

	PAGE
organisms, 100; Reticulo-endothelial system in chemotherapy, 104; Mode of action, 105; Helminthic infections, 106; Protozoal infections, Emetine, Quinine, 107; Antimony, 108; Arsenic, 110; Bacterial and virus infections, 112.	
CHAPTER VI. PHYSIOTHERAPY	116
Hydrotherapy, 116; Mineral waters, 121; Electrotherapy, 125; Radiations in therapy, 131; Ultra-violet lights, 132; X-rays, 134; Radio-therapy, 136; Method of administration of radium, 140; Mild radium therapy 141; Intensive radium therapy, 142.	
CHAPTER VII. DIET AND DIETETICS IN THE TROPICS	146
Food and its constituents, 146; Relative value of foods 147; Determination of the merits of food-stuff, 148; Amount of food required in health, 152; Mineral constituents of food, 153; Water, 154; Indian dietary, 159; Errors of diets in the Tropics, 162; Diet in disease, 166; Diet during pregnancy, 170; Diet during lactation, 173; Diet during infancy and childhood, 174; indications for special modifications, 175; Feeding of older children, 176; Vitamins, 176.	
CHAPTER VIII. PYREXIA	202
Body temperature, 202; Regulation against over-heating, 205; Regulation against over-cooling, 206; Pyrexia and its treatment, 207; Antipyretic drugs, 212; Therapeutic application of antipyretic measures, 216; Heat stroke, 218; Stroker's cramps, 221.	
CHAPTER IX. PAIN AND INSOMNIA	223
Insomnia and use of hypnotics, 223; General measures and drugs, 224; Barbituric acid derivatives, 227; Bromides, 231; Analgesics, 232; Opium alkaloids, 232; Morphine derivatives, 233; Aromatic analgesics, 234.	
CHAPTER X. TONICS	236
General tonics, 236; Bitters, 236; Strychnine, 237; Alcohol, 238; Thyroid, 239; Arsenic, 239; Calcium, 240; Iron, 240; Phosphorous, 241; Cardiac tonics, 241; Heart failure 244; Digitalis, 246; Strophanthin, 249; Camphor and its derivatives, 249; Caffeine, Adrenalin, 250; Ephedrine, Quinidine, 251; Glucose, Cane-sugar, Oxygen, Morphine, 252.	

PART II

REMEDIES USED AGAINST HELMINTHIC DISEASES

CHAPTER I. GENERAL CONSIDERATION	254
Those which live in the gastro-intestinal tract, 254; Those which live in the tissues of the body and cause somatic infections, 255; Administration of anthelmintics, 256; Criteria of	

CONTENTS

xv

	PAGE
cure, 261; Choice of anthelmintics, 263; Intestinal helminthiasis, 266; Nematodes, 267; Cestodes, 269.	
CHAPTER II. ANTHELMINTICS ACTING ON CESTODES	271
Male fern and allied drugs, 271; Aspidium, 271; Koussou or cusso, 276; Kamala, 278; Other anthelmintics, 279.	
CHAPTER III. ANTHELMINTICS ACTING ON NEMATODES	284
Carbon derivatives, 284; Carbon tetrachloride, 284; Carbon tetrachloride and chenopodium, 291; Other carbon derivatives, 293; Tetrachlorethylene, 294.	
CHAPTER IV. ANTHELMINTICS ACTING ON NEMATODES (CONTD.)	298
Essential oil group, Oil of chenopodium, 298; Other essential oils used as anthelmintics, 303.	
CHAPTER V. ANTHELMINTICS ACTING ON NEMATODES (CONTD.)	307
Santonin, 307; Santonin and chenopodium, 310.	
CHAPTER VI. ANTHELMINTICS ACTING ON NEMATODES (CONTD.)	313
Thymol and allied compounds, 313; Thymol, 313; Beta-naphthol 319; Resorcinol derivatives, 322; Hexylresorcinol, 322; Heptylresorcinol, 324.	
CHAPTER VII. MISCELLANEOUS ANTHELMINTICS	326
Intestinal antiseptics, Purgatives, 326; Heavy metals, Embelia ribes, Azadirach, Corsican moss, Mucuna, Butea frondosa, 327; Ficus laurifolia, Quassia, Spigelia marilandica, 328; Chrysanthemum cinerariæ, Rhumunus cathartica, Allium sativum, Geraniol, Acalypha indica, etc., 329.	
CHAPTER VIII. ANTHELMINTICS ACTING ON SOMATIC PARASITES	330
Trematode infections, 331; Schistosomes, 332; Cestode infections, Nematode infections, 333; Filariasis, 335; Arsenic compounds, 338; Antimony compounds, 339; Emetine and other drugs, 343; Aniline dyes, 345.	

PART III

REMEDIES USED AGAINST PROTOZOAL DISEASES

Classification of drugs acting on protozoal infections, 350;
Vaccine therapy in protozoal diseases, 351.

SECTION I. REMEDIES USED AGAINST AMOEBIASIS

CHAPTER I. GENERAL CONSIDERATION	356
Incidence of amoebiasis, 356; Latent infection and carriers, 358; Diet in amoebiasis, 359.	
CHAPTER II. IPECACUANHA AND ITS ALKALOIDS	360
Substitutes of ipecacuanha in the market, 361; Pharmacology of emetine, 363; Pharmacology of other alkaloids, 366.	

	PAGE
CHAPTER III. EMETINE IN AMOEBIASIS	387
Acute and sub-acute amoebic dysentery, 369; Emetine in relapsing and chronic dysentery, 370; Amoebic hepatitis and liver abscess, 374; Amoebic liver abscess, 375; Dosage and modes of administration, 377.	
CHAPTER IV. COMPOUNDS OF IPECACUANHA AND EMETINE	381
Emetine adsorbate, Emetine-bismuth-iodide, 381; Emetine periodide, 385; Aur-emetine, 386; Emetol, Par-emetol, Arsemetine, Gavano, etc., 387.	
CHAPTER V. TOXIC EFFECTS OF EMETINE	390
Cumulative toxic effects, 390; Emetine neuritis, 392; Emetine diarrhoea, 393; Cautions and contraindications, 394; Emetine in pregnancy, 395.	
CHAPTER VI. MODE OF ACTION OF EMETINE	396
CHAPTER VII. OTHER AMOEBICIDAL REMEDIES	398
Holarrhena antidysenterica, 398; Yatren, 405; Organic arsenicals, 409.	
CHAPTER VIII. PALLIATIVE REMEDIES IN AMOEBIASIS	415
Plantago ovata, 416; Aegle marmelos, 418; Acorus calamus, 419; Helicteres isora, Castela nicholsoni, 420; Simarubra bark, Uzara, 421.	
CHAPTER IX. DRUGS USED AGAINST FLAGELLATE DIARRHOEA	422
SECTION II. REMEDIES USED AGAINST LEISHMANIASIS AND TRYPANOSOMIASIS	
CHAPTER X. ANTIMONY AND ITS DERIVATIVES	429
Pharmacological action, 430.	
CHAPTER XI. THERAPEUTICS OF ANTIMONY COMPOUNDS	436
Kala-azar or visceral leishmaniasis, 436; Trivalent compounds, 436; Pentavalent or organic aromatic compounds, 440; Relative value of pentavalent compounds in the treatment of kala-azar, 444; Antimony in other affections, 448; Dermal and mucocutaneous leishmaniasis, 450.	
CHAPTER XII. COMPOUNDS OF ANTIMONY	454
Inorganic compounds, Trivalent compounds, 455; Aromatic compounds, 456.	
CHAPTER XIII. TOXIC EFFECTS	460
Complications due to antimonyl tartrate injections, 460; Complications after injections of pentavalent compounds, 461.	
CHAPTER XIV. MODE OF ACTION OF ANTIMONY COMPOUNDS	464
CHAPTER XV. REMEDIES USED AGAINST TRYPANOSOMIASIS	466
Germanin or Bayer "205", 466; Other drugs in trypanosomiasis, 472.	

CONTENTS

xvii

PAGE

SECTION III. REMEDIES USED AGAINST MALARIA

CHAPTER XVI. GENERAL CONSIDERATION	478
Incidence of malaria, 478; Epidemiology, 479; Study of cures, 483.	
CHAPTER XVII. CINCHONA ALKALOIDS	490
CHAPTER XVIII. PHARMACOLOGICAL ACTION OF CINCHONA ALKALOIDS	499
CHAPTER XIX. THERAPEUTICS OF CINCHONA ALKALOIDS	515
Quinine in malaria, 516; Modes of administration, 527; Treatment of special forms, 539; Other cinchona alkaloids in malaria, 544.	
CHAPTER XX. TOXIC EFFECTS OF QUININE	553
Quinine idiosyncrasy, 554; Cinchonism, 555; Quinine albuminuria, 556; Visceral degeneration, 557.	
CHAPTER XXI. MODE OF ACTION IN MALARIA	559
Action of cinchona alkaloids on gametes, 562; Immunity production, 565.	
CHAPTER XXII. PROPHYLAXIS AGAINST MALARIA	567
Quinine prophylaxis, 568.	
CHAPTER XXIII. QUININE IN BLACKWATER FEVER, AND OTHER AFFECTIONS	574
Blackwater fever, 574; Pneumonia, Common cold, Exophthalmic goitre, Diseases of the circulatory system, Quinine in induction of labour, etc., 579.	
CHAPTER XXIV. PREPARATIONS OF CINCHONA BARK AND ITS ALKALOIDS	582
Crystalline alkaloids, 582; Amorphous alkaloids, 589.	
CHAPTER XXV. OTHER ANTIMALARIAL REMEDIES	590
Plasmoquin, 590; Atebrin, 602; Tebetren and malarcan, 609; Other drugs, 611.	
CHAPTER XXVI. PRESENT POSITION OF ANTI-MALARIAL DRUG THERAPY	617
Treatment of attack, 617; General management, 620; Specific drug therapy, 622.	

SECTION IV. REMEDIES USED AGAINST SPIRAL ORGANISMS

CHAPTER XXVII. ARSENIC AND ITS DERIVATIVES	635
Pharmacological action, 635; Organic Compounds of arsenic 640; Classes of organic arsenic compounds, 643.	
CHAPTER XXVIII. THERAPEUTIC USES OF ARSENICALS	646
Helminthiasis, Malaria, 647; Trypanosomiasis, 648; Dengue, 650; Intestinal protozoal and other infections, 651; Diseases produced by spirochaetes or spirilla or spirochaeta, 651; Rat-bite fever, 652; Syphilis, 653; Syphilis of the central nervous system, 654; Framboesia, 655; Vincent's angina, Other conditions, 656; Modes of administration, 657.	

	PAGE
CHAPTER XXIX. ORGANIC COMPOUNDS OF ARSENIC	661
Atoxyl, 661; Tryparsamide, 663; Stovarsol, 668; Treparsol, 672; Trivalent compounds of arsenic, Salvarsan, 673; Neo-salvarsan, 674; Co-ordination compounds, 676; Standardisation of salvar- san and allied compounds, 682.	
CHAPTER XXX. TOXIC EFFECTS OF ARSENIC COMPOUNDS	685
Acute poisoning, Chronic poisoning, 685; Toxicity of organic compounds, 686; Dermatitis and allied reaction, 691; Syphilitic and arsenical jaundice, 695; Cautions and contraindications, 700.	
CHAPTER XXXI. BISMUTH AND ITS DERIVATIVES	703
Pharmacological actions, 704.	
CHAPTER XXXII. THERAPEUTIC USES OF BISMUTH	708
Syphilis, 708; Effect on serological reactions, 710; Neurosyphilis, 711; Prophylactic effects in syphilis, 712; Yaws or frambœsia, 712; Amoebic dysentery, 713; Lupus erythematosus, 714; Modes of administration, 715.	
CHAPTER XXXIII. TOXIC EFFECTS OF BISMUTH	717
Preparations of bismuth, 721.	
CHAPTER XXXIV. MERCURY AND ITS DERIVATIVES	728
Pharmacological actions, 728.	
CHAPTER XXXV. THERAPEUTIC USES OF MERCURY	735
As antiseptic, As cathartic, 735; In syphilis, 736; Prophylactic uses, 738; As diuretic, 738; In septicæmic condition, 739; Skin diseases, Gonorrhœa and gleet, 740; Asthma and hay fever, Bilharziasis, 741; Modes of administration, 741.	
CHAPTER XXXVI. TOXIC EFFECTS OF MERCURY	745
Preparations of mercury, 747.	

PART IV

REMEDIES USED AGAINST BACTERIAL AND VIRUS DISEASES

CHAPTER I. GENERAL CONSIDERATION	760
Chemotherapy of bacterial diseases, 763.	
CHAPTER II. SPECIFIC IMMUNE THERAPY IN BACTERIAL AND VIRUS DISEASES	772
Vaccine therapy, 773; Therapeutic uses, 781; Serum therapy, 791; Bacteriophage therapy, 808.	
CHAPTER III. BOWEL DISEASES	823
General management, 826; Intestinal antiseptics, 827; Enteric fever, 830; Bacillary dysentery, 840; Chronic ulcerative colitis, 846; Coliform infection, 860; Cholera, 854; Food-poisoning, 869; Botulism, 876; Diseases conveyed by food, 878; Sprue, 879; Hill diarrhœa, 884.	

CONTENTS

xix

	PAGE
CHAPTER IV. OTHER BACTERIAL DISEASES	888
Cerebrospinal fever, 888; Plague, 887; Undulant fever, 907; Oroya fever and verruga peruana, 911.	
CHAPTER V. REMEDIES USED AGAINST LEPROSY	914
Chaulmoogra oil, 917; Pharmacological action, 921; Therapeutic uses, 923; Sodium salts of fatty acids of chaulmoogra and hydno- carpus oils, 926; Ethylesters of chaulmoogra oil, 929; Other oils used in leprosy, 933; Heavy metals, 934; Miscellaneous remedies, 935.	
CHAPTER VI. TUBERCULOSIS	945
Clinical varieties of tuberculosis, 949; Prophylaxis, 957; Treat- ment of pulmonary tuberculosis, 958; Chemotherapy, 963; Symp- tomatic treatment, 969.	
CHAPTER VII. VIRUS DISEASES	971
Typhus and allied fevers, 975; Typhus fever or typhus exanthema- ticus, 976; Tick typhus, 977; Mite typhus, 978; Influenza, 983; Dengue, 987; Sandfly fever, 989; Yellow fever, 990; Small- pox, 996; Rabies, 1004; Lymphogranuloma inguinale and clima- tic bubo, 1009; Granuloma venereum, 1011.	

PART V

REMEDIES USED AGAINST MISCELLANEOUS TROPICAL DISEASES

CHAPTER I. NUTRITIONAL DISORDERS	1018
Beriberi, 1018; Epidemic dropsy, 1023; Pellagra, 1029; Lathy- rism, 1036; Infantile biliary cirrhosis, 1039.	
CHAPTER II. METABOLIC DISORDERS	1043
Diabetes mellitus, 1043; Hypoglycæmic and diabetic coma, 1049; Obesity, 1051.	
CHAPTER III. TROPICAL NEURASTHENIA	1059
Ætiology and incidence, 1060; Exciting causes, Predisposing factors, 1061; Heredity, Diet, Exercise, 1062; General endocrine dysfunction, 1063.	
CHAPTER IV. POISONOUS ANIMALS	1067
Snake venoms, 1067; Classification and identification of snakes, 1067; Venom of Indian cobra, 1072; Snake venoms in therapy, 1097; Other venomous animals, 1105.	
CHAPTER V. DRUG ADDICTION AND ITS TREATMENT	1116
Drug addiction in India, 1117; Opium, 1117; Administration of opium to infants, 1119; 'Post,' Opium alkaloids, Indian hemp, 1120; Alcohol, Cocaine, 1121; New drug habits 1122; Treatment of drug addiction, 1125.

INDEX 1731

A HANDBOOK OF TROPICAL THERAPEUTICS

PART I

GENERAL CONSIDERATIONS IN THERAPY

CHAPTER I

ACTION OF DRUGS

The source and nature of drugs. From the remotest times man has looked for remedies to alleviate sufferings, the problem of cure of disease has faced mankind as far back as memory can take us and the evolution of drugs is traceable to the desire of man to overcome personal discomfort and disease. In course of time the knowledge of drugs and with it their number and uses have gradually increased. Although modern science has opened up new sources of remedies from the mineral resources and the animal kingdom, reliance is still placed to a great extent, upon plant life for the supply of drugs. The plants may occur in nature or they may be cultivated; they are collected and active preparations are made from them. The very name drug comes from the Anglo-Saxon word *drugon* meaning to dry. Crude drugs are the commercial form of plant drugs as they are brought to the market. They yield one or more definite chemical bodies of medicinal value which are known as active principles or active constituents. These constituents may occur in the whole plant or in one particular part, *e.g.*, roots, leaves, seeds, etc.

Besides the drugs of vegetable origin, there is another group of drugs known as chemicals. Many chemical compounds are produced by plants, by natural processes at ordinary temperature and pressure, *e.g.*, alkaloids, glucosides, salts, etc. To produce similar compounds artificially, the chemist has to resort to powerful reagents such as strong acids and alkalis, large variations

in temperature and pressure, distillation, fusion and many other drastic operations. Many of the products of the chemist are similar in action and composition to natural compounds, but they are cheaper to produce. Other chemicals belonging to the inorganic class are produced from natural minerals, sometimes by simple processes at other times by complicated ones. Then there are comparatively recent remedial agents obtained by various chemical operations, mainly from coal tar as well as other products obtained by the more or less complicated processes of synthesis. There are also the so-called organometallic compounds which form a powerful and important group, particularly in the treatment of protozoal diseases. These compounds have to be prepared with extreme care, as many of them would be positively dangerous, unless they are in a state of absolute purity.

The biological products, such as vaccines, sera, gland products, hormones, bacteriophages, etc., form another group of remedial agents. They require even greater skill and more expert knowledge than any other type of preparation used in medicine.

Action of drugs as basis of therapy. Pharmacology is the term applied to the science which deals with the action of drugs upon animal organism without special indication to their application in disease. It, in fact, denotes the physiological action of drugs, which forms the basis for their scientific use in curing diseased conditions, the alleviation and prevention of pain and prolongation of life. Experimental pharmacology deals with the reactions of living material to changes in environment, these changes being produced by drugs.

Therapeutics has been defined as the art and practice of treating abnormal states by any method that relieves pain, restores health or prolongs life. It comes from the Greek word *therapeutikas* meaning healing, curative, alleviative. It includes all remedial agents and measures used in the treatment of disease. Therapeutics may be empirical or rational. The former includes any measure which experience has shown to be beneficial but whose action cannot be explained, e.g., colchicum in gout; the latter consists in using drugs whose mode

of action is understood, *e.g.*, quinine in malaria. Some of the sub-division of therapeutics according to McGuigan are:—

(a) Mechanical, which includes the use of bandages, splints, dusting powders, petrolates, catheterization, massage, gymnastics.

(b) Drug or chemical therapeutics, which includes all substances acting chemically—therefore most drugs.

(c) Physical therapeutics or the use of heat, cold, electricity in various forms, or radium.

(d) Heliotherapy consists in using sunlight and other forms of light as therapeutic agents.

(e) Hydrotherapy or the use of water in all forms; ice, cold water, hot water, steam in the form of baths, packs, douches.

(f) Suggestive or psycho-therapeutics, includes suggestions, advice, hypnotism, or anything that will console or encourage the patient and so promote his welfare.

(g) Dietetic therapeutics or the regulation of the food, is always extremely important in the treatment and prevention of disease.

(h) Preventive medicine in a large degree may be considered a branch of therapeutics. It includes the use of all available hygienic measures in the prevention of disease or the limiting of its spread.

In the treatment of disease full use should be made of all these measures. In the improvement produced in the condition of the patient by application of these measures the part played by nature must not be forgotten. Nature is infinitely wiser in medicine and surgery than we imagine. Variations from normal in disease are often an effort on the part of nature to meet the needs of the patient and should not always be considered as harmful. Proper use of therapeutic measures renders important help to these forces in curing disease in the least time and with least harm to the organism. The task of the physician consists in directing the treatment in such a manner as to remove the obstacles which hinder the path of natural cure. This should be done by a thorough comprehension of the

diseased conditions, that is by diagnosing the case as carefully and as fully as possible. Before ordering a drug or method of treatment the physician should have a clear conception of what he is trying to accomplish. Drugs should not be prescribed unless there is a distinct indication for them. The doses of all the remedies should be very carefully considered, to fit the needs of the patient's condition. Special regard should be paid to such influential factors which have an important bearing on the treatment of disease as, the maintenance of the vitality of the patient by proper feeding, elimination of toxins by the kidneys, bowels and skin, relief of annoying symptoms, and giving to the patient sufficient physical and mental rest and sleep. Physicians should not be contented with the relief of symptoms alone but should strike at the root cause of disease. Unfortunately for a large majority of the diseases attacking man specific remedies do not exist. The progress of chemotherapy during recent years has produced a number of effective remedies against protozoal diseases, but drugs specifically attacking bacterial infections in the human body have not yet been discovered.

The mode of action of drugs. The drugs may act independently outside the body (antiseptics on micro-organisms), they may act in or about the body, but not on its structures (sulphur on ringworm of skins) and lastly they may act on the tissues of the body itself. On the tissues of the body the drugs may act by physical or chemical means.

(a) **Physical actions.** In these no chemical reaction occurs between the drug and the tissues. The examples of physical action are the protective effect of oils, dusting powders, etc.; osmotic effects or salt actions of isotonic, hypotonic or hypertonic solutions; adsorptive or absorptive action of carbon dyes, infusorial earths and the colloids generally.

(b) **Chemical actions.** Some drugs exert chemical reactions within the body which may be of the nature of combination or substitution. By combination is meant the direct union of the drug with the tissues of the body or with the products of secretion. Acids may unite with ammonia or with alkaloids to form addition compounds. Similar combinations may occur

with protein. The action of general anæsthetics is due to direct combination. Substitution occurs when the hydrochloric acid of the stomach is neutralised by sodium bicarbonate or the combination of calcium solution with oxalates to form inert insoluble compounds. Such unexplained reactions as selective affinity are probably chemical and may be either combination or substitution.

According to Straub the action of a drug is often due to the differences of concentration within and without the cell. Some drugs only act while they are penetrating the cell or while the concentration inside and outside the cell is different.

Selective or specific action. Selectivity is a phenomenon widely distributed in nature. The eye selects certain vibrations which are called light; other vibrations beyond the ordinary colour limit are unnoticed. The colour of objects is due to selective absorption. Foods and drugs are readily absorbed from the gastro-intestinal tract, cathartics are not. Carbon absorbs some gases and colouring matter to the exclusion of others. Platinum and palladium absorb some gases and not others. Selective oxidation occurs in the body, thus if 2.0 gm. of benzene are given to a man 0.8 gm. of phenol is formed, but if it is combined with 2.0 gm. of alcohol, all the alcohol is oxidised and only 0.33 gm. of phenol is formed. Selective actions in the body are apt to be modified by disease; sugar is readily oxidised in health but not in diabetes. The action of colloids may be selective. Other cases of selection may be explained on a physical or electrical basis.

The body cells show selective phenomena. The renal cells are very permeable to sulphates, the intestinal cells very slightly so. By virtue of this peculiarity the cells are capable of preserving their own composition notwithstanding the composition of the fluid in which they are bathed. This explains why a substance acts more strongly upon one cell than upon another. The differences are seen in case of the dyes. The difference in absorption may be due to the cell envelope and partly to the cell contents. Lipoid solvents generally penetrate better than other agents. The distribution of a drug is often modified by its reaction, or by the presence of a second

substance, such as oxygen. Iodides and acridine dyes are taken readily by degenerating tissues, such as, caseous material.

Most of the drugs exert their action by their chemical affinity for one or other constituent of protoplasm. The living cell may be considered as a complex laboratory, where chemical decomposition, synthesis, reduction and oxidation are constantly going on. Drugs act by altering these processes so that either the functional power of the cell or actual cell structure is changed. Some of these are general in their action, minute quantities affecting practically all forms of protoplasm in the body (though not all forms in the same degree) and when the action of drugs is powerful they are known as general protoplasmic poisons, *e.g.*, hydrocyanic acid, quinine, etc. To test the general protoplasmic poisons the effect is studied on bacteria, yeasts, white blood corpuscles, amoebæ, ciliary movements, spermatozoa, etc., *i.e.*, protoplasm undifferentiated into tissues or organisms. If the drug acts on these organisms, it is a general protoplasmic poison or has a general action. Some exert a selective action on a certain special tissue or tissues leaving the others unaffected. This is presumably owing to a chemical affinity for some component of the particular cells or group of cells. These are said to have a selective specific action. Strychnine has selective affinity for certain portions of the central nervous system, pilocarpine for secretory nerve endings, epinephrine for the sympathetic endings, atropine for parasympathetic nerve ending, picrotoxin for the medulla, etc.

It is suggested that during the production of specific effect the active drug is in some sort of combination with a chemical substance contained in the body of the cell acted upon and it is generally assumed that this combination is of a chemical nature. Adrenalin in producing its effect, is taken up and destroyed by the sympathetic nerve endings; strychnine forms a loose combination with the cells of the cord for it is all recovered from the urine unchanged, morphine comes midway between adrenaline and strychnine as it is partly destroyed in the tissues and if the animal is tolerant, destruction is much greater than normal.

Toxic effects. If drugs are given in adequate doses they produce therapeutic effects, but if larger doses are given they act as poisons. Poison comes from the Latin word *potio* meaning a draught. By poison is meant any substance, administration of which will injure health or cause disease. These effects may be immediately manifested or they may take some time to occur. Toxicology comes from the Greek word *toxikon* meaning a poison. It deals with the symptoms, diagnosis, treatment and detection of poison. As a large number of the drugs used in the treatment of disease are potent substances, their dosage and the length of period during which they are to be administered should be very carefully considered.

The nature and results of drug action. The fundamental properties of living matter as compared with dead matter are :—
(1) Metabolism, *i.e.*, functioning of anabolic and katabolic processes. This includes nutrition or assimilation, which includes digestion, secretion, absorption and excretion. (2) Excitability as manifested by contractility, conduction, irritability and secretion. (3) Reproduction.

Drugs can only modify these properties, they cannot create new functions. The changes produced by the drug are quantitative only. The smallest live unit is a cell and the body tissues are made up of infinite number of these cells. The effect of drugs on cells is to stimulate them, to depress them or to change or destroy them. Stimulation is an effect on cells by which their power or their readiness to function is increased. It is often impossible to separate stimulation and sensitisation. Normally all movements are increased by stimuli acting on nerve centres. Depression is a decrease in function due in most cases to decreased sensitivity. In irritation the change is more anatomical than functional, and some of the signs of inflammation (redness, rise of temperature, swelling and pain) are present. Drugs may cause fatigue and paralysis which are also modifications of function. The causes of fatigue may be :—(1) exhaustion of energy-yielding material, (2) accumulation of waste products. Fatigue occurs in the following order in tissues :—nerve centres, nerve endings, muscles and nerve fibres.

Recovery from fatigue takes place with rest alone. Paralysis may be produced by drugs and is due to a combination (chemical) of the drug with the cell substance; recovery takes place only after the drug is removed. Paralysis may also be caused by anatomical changes or lesions and in some cases recovery cannot be expected. In many cases fatigue and paralysis cannot be distinguished and in such cases both the elements usually enter into the action. Often a drug is found to stimulate one structure and depress another, *e.g.*, atropine stimulates the vagus centre and depresses the vagus endings; pilocarpine stimulates the nerve endings in sweat glands and depresses heart muscle.

The intensity of the action of a drug depends on, (a) the concentration in which it reaches the particular cells on which it acts and, (b) the duration for which this concentration is maintained. The concentration which a drug attains in the body depends on:—(1) The rate of its absorption, and (2) the rate of its removal from the body which occurs in two ways:—(a) Excretion by kidneys, lungs, skin, etc. (b) Chemical destruction in the body by compounds, processes of oxidation or reduction, or by the formation of inert bodies in combination with such compounds as glycuronic acid and sulphates.

Absorption and distribution of drugs. The local action of drugs occurs without absorption and general action only occurs after absorption. There may however be local, general and specific actions from the same substance, *e.g.*, phenol. In many cases the object of administration is that they may be absorbed into the blood and produce their specific effects. For this purpose a drug may be (1) applied to the skin, but here absorption takes place with difficulty, as it has to be completed through the sweat glands, the horny epithelium of the skin being impermeable; (2) when administered by the mouth the drugs are absorbed from the gastro-intestinal tract; (3) when injected subcutaneously, intramuscularly, intravenously or into one of the serous sacs absorption rapidly takes place.

When given by the mouth, which is the commonest mode of administration, drugs are absorbed principally by the upper portion of the small intestine; very little absorption occurs from the stomach though alcohol and strychnine are absorbed

slowly from it. Experiments have shown that the isolated rectum absorbs at least as well as the small intestines, owing to its abundant vascularity. Strychnine $1\frac{1}{2}$ grain put directly into the stomach of an animal produces convulsions in 30 minutes, in the small intestines in 10 minutes, in the œsophagus in 50 minutes, in the colon in 14 minutes and in the rectum in 7 minutes. From the stomach most drugs are absorbed slowly under ordinary conditions. Alcohol is, however, an exception and is not only absorbed rapidly but accelerates absorption of other substances dissolved in it, because its irritating effect improves the circulation. Such effects are reversible and the absorption of alcohol may be slowed by non-absorbable drugs like cascara sagrada. Substances like oleo-resin of male fern are absorbed more quickly from solution in oil than in water. Absorption from both the stomach and intestine is influenced considerably by the amount of food present and in some cases the food enters into combination with the drug. Absorption is more rapid from the empty than from the full gastro-intestinal tract. Absorption occurs readily from the small and more slowly from the large intestines. Foodstuffs that are not absorbed from the small intestines, are often absorbed from the large gut. In medical practice rectal feeding has sometimes to be resorted to in persons unable to swallow; predigested foods and glucose are readily taken up. Toxins are also absorbed in the same way. The rate of absorption depends on the method of administration of a drug and occurs in the following order beginning with the most rapid, intravenous, intraperitoneal, hypodermic routes, through mucous membranes of sublingual region, nose, stomach, rectum and from skin. Conditions affecting the alimentary canal also modify absorption, thus in shock absorption is considerably decreased. Slight irritation of the gut which does not cause injury may facilitate absorption. Pronounced injury may decrease it; ulceration of the mucous membrane increases the absorbability of many drugs. Astringents tend to lessen absorption, and saline solutions such as magnesium sulphate and other cathartic drugs, which are but little absorbed themselves, may prevent the absorption of other drugs and even water.

The mechanism by which the mucous membrane of the gut allows the ready absorption of some substances and inhibits that of the others is not understood. Why K or Cl ions are absorbed and SO_4 and Mg ions are not, is not clear. The intestinal epithelium undoubtedly must have some selective power. It should also be noted that the presence in the alimentary canal of non-absorbable substances hinders absorption of others, *e.g.*, absorption of strychnine in the isolated piece of gut is delayed in presence of magnesium sulphate. Some gases such as hydrocyanic acid, phosgene, nitrous oxide, and ethylene are absorbed rapidly by the lungs, while ammonia is but little absorbed.

Only soluble substances can be absorbed, but it should be remembered that solubility is modified by chemical changes in the alimentary canal; insoluble substances are rendered soluble by the action of juices and are then taken up. Solid substances such as carbon, iron, etc., are taken up through the agency of phagocytes and may be found in the mesenteric blood and lymph nodes. Such solids exert no action unless dissolved in the body fluids. The rate of absorption is modified by the solvent. Solutions in alcohol are more rapidly absorbed than water solutions. The more soluble a substance is in protoplasm, the more quickly it is absorbed. The concentration of the solution may vary the rate of absorption. The absorption area modifies the rate of absorption, *e.g.*, multiple hypodermic injections are absorbed much more quickly than if the same amount of fluid were injected in one place at once.

Volatility is another factor which influences absorption. Hydrocyanic acid is absorbed rapidly and causes instantaneous death when concentrated. Most volatile substances if swallowed are rapidly absorbed from the gastro-intestinal tract. Colloids such as gums and resins, oils, kaolin (Fuller's earth) charcoal and other inert powders and plant residues, when mixed with absorbable materials such as salts and alkaloids, lessen the rate of absorption—partly by fixing themselves to the drug and partly by hindering access to the absorbing surface. Isolated active substances (alkaloids) are, therefore, preferred if quick systemic action is desired, while galenical preparations (extracts, tinctures, pills, etc.), are used for local

effects. No general action may take place if the excretion of a drug is as rapid as its absorption, because the effective concentration cannot be maintained.

Rapidity of absorption is proportional to the rapidity of the circulation and flow of lymph through the part. In cases of heart disease where there is stasis in the circulation of the intestine, digitalis may be poorly absorbed, and this accounts for the failure of digitalis therapy in these conditions. For the same reason lesions of the spinal cord delay absorption. Vasoconstriction and catarrhal conditions of the intestines may also reduce absorption. Excessive distension of the gut decreases the rate of absorption by slowing the blood and lymph flow. Although drugs like arsenic may travel for a considerable distance through dead bodies and strychnine, morphine, fuchsin, epinephrine, etc., have been shown to be absorbed in frogs with the heart removed, absorption normally takes place only when the circulation is intact. In the alimentary canal, injury to absorbing cells may either facilitate or hinder absorption.

Absorption by the blood and lymph. Most soluble substances are absorbed from the alimentary canal by the blood rather than by the lymph and this is also true of serous cavities. Such substances as methylene blue, methanamine and some other drugs injected into the pleural sacs appear in urine before they are seen in the thoracic duct. All these drugs, however, may be detected in the lymph. Some potent toxins such as tetanus and diphtheria when injected locally, follow the nerve sheath to the central nervous system. Such toxins are more active when given intramuscularly or subcutaneously than when given intravenously, because by the last route they reach the centres in a more diluted form.

A large number of drugs are either not absorbed at all or only in minute amounts. Of the common metals only arsenic and mercury are readily taken up and both of these are volatile; most of the heavy metals are absorbed so slowly that weeks or months of ingestion may be required to produce poisonous effects. Injection into the circulation of the same amount of iron, as given by mouth, may be attended with serious results.

The difference in toxicity here is largely a question of absorption.

Absorption through the skin in man is very slow, though some substances such as methyl salicylate may be rapidly absorbed. The skin of young children is more permeable and death has occurred by application of methyl salicylate in this way. Absorption occurs more rapidly from regions where the epidermis is thin, *e.g.*, axillae, groins, inner surface of arms and thighs. That is the reason why inunctions are given in these regions. Potent drugs such as atropine and aconite, should be applied with care. If absorption is required from the skin, the drug should be incorporated with lanoline or lard. Lanoline is said to carry the drug to the tissues, lard to the skin only and petroleum to the surface of the skin. Absorption occurs quickly from the pleural and peritoneal cavities. Hyper-tonic salt solutions first draw water from the blood and when they are isotonic they are rapidly absorbed.

Absorption is delayed by emotional states; fear, pain and sorrow may seriously interfere with the emptying of the stomach, digestion and absorption. Many pathologic conditions delay absorption. Absorption of fat is delayed in tuberculosis of the intestines on account of destruction of the lymphatics. In extra-intestinal tuberculosis the absorption of all types of food materials is reduced by one-half. Deficient circulation delays absorption, some absorption occurring through osmosis and diffusion even in the absence of circulation.

Some drugs produce their effect because they are not absorbed. A good example of this is the purgative group of drugs. Unabsorbability is the essential of a good purgative. It is for this reason that pure crystalline active principles are not good as purgatives, since in this form absorption is facilitated.

Sojourn of drugs in the blood. A drug, once it is absorbed into circulation, stays in the blood for a short time, because it must penetrate into the tissue cells to produce its effect. The passage of the absorbed or injected substances from the blood into the tissues is a rapid process for diffusible substances and materially slower for colloids. Intracellular absorption is a very

rapid process and depends on the nature of the drug and to some degree on its concentration. Toxic doses of arsenic, after intravenous injection, disappear completely from the blood in less than 30 seconds, diphtheria toxins take 4 minutes, cyanides 2—6 minutes; anti-toxin circulates for several hours. A group of dyes remain for longer periods in the plasma, another group are rapidly excreted by the urine; and a third group disappear from the plasma, but are not excreted by the kidneys.

Distribution of drugs in the body. This is not a uniform process. Drugs accumulate particularly in certain cells, according to their permeability and physical and chemical affinities. These influence their action either by bringing them in contact with reactive tissues, or storing them in places where they may be inactive. Iodine is stored in the thyroid gland as iodothyron; bones retain earthy metals and fluorides; heavy metals are deposited as loose organic compounds in the liver and the spleen; mercury as a loose globulin compound; arsenic as a more stable nuclein combination occurs in the liver, bone marrow, skin, etc., chlorides, bromides and related ions accumulate in all organs but mainly the skin and the blood. Little is known about the distribution of organic poisons, mainly for want of suitable assay methods.

Changes in drugs during absorption. The majority of drugs are altered in the body by processes of oxidation, reduction, hydration, dehydration or decomposition; by storage in certain organs, or combination with other substances, toxic drugs are rendered harmless. This process of detoxication is of very great importance as it renders the continuous administration of drugs (in most cases in increasing doses) an absolute necessity. If it were not for this power of the organism to destroy and remove poisons and thereby to recover from its action, all therapeutic uses of drugs would have been an impossibility. On the other hand, the alteration of the drug by the body may result in the formation of more toxic substances (nitrites) or the drug may be rendered more effective therapeutically. The digestive juices destroy some organic poisons by hydrolytic changes (glucosides, proteins and anti-toxins). They are also necessary to saponify and liberate

the active constituents of insoluble esters (phenyl salicylates). The acidity of gastric juice is of importance in the solution of bases.

The tissues play a part in decomposing toxic drugs. Strychnine, morphine and many other alkaloids are partly oxidised in the tissues and thus rendered inert. Many organic acids, alcohols and formaldehyde are detoxicated by oxidation. The organic compounds of metals (*e.g.*, cacodyles) only develop their metal action after oxidation. The thyroid gland is said to play an important part in destruction of poisons in the body and its excision increases the toxicity of many poisons. The liver is believed to be a great disintoxicating organ, acting partly by destroying poisons and particularly by storing them. That is the reason why the same dose is much less effective when given into one of the mesenteric veins than when given by the jugular vein. This has been shown to be the case with curare, strychnine, morphine, cocaine, narcotine, quinine, atropine and the metals. Perfusion of alkaloids, glucosides, toxins, barium, etc., through the excised liver decreases their toxicity. Perfusion through excised muscle also produces disintoxication, but its action is weaker than that of the liver, in case of chloral, atropine, physostigmine, alcohol, etc. Excision of the spleen is said to increase the toxicity of most alkaloids, but not all. The phagocytes accumulate and thus disintoxicate many poisons, especially the colloids. The serum of atropine-resistant animals (rabbit) destroys atropine.

Adsorption. Adsorption comes from the Latin word '*Sorbere*' meaning to suck. It is the power possessed by certain substances of retaining on their surfaces gases, liquids, and solids, either in solution or in the colloidal state. One substance here becomes a part of another and remains in a state midway between mechanical mixture and chemical combination. This phenomenon plays a very important part in the action of drugs. The disintoxication is sometimes carried out through adsorption, thus pilocarpine is detoxicated for excised intestine by digestion with serum; but it may be fully recovered from it in active form by extraction with acid or alcohol, showing that it was not destroyed. The nature of adsorbing substances is not

known, but it is found in abundance in rabbit's serum, less in that of cats or oxen, and it is absent in dog's blood.

Disintoxication by combination. Phenols and other aromatic compounds are rendered less toxic by combining with sulphates; many metals are detoxicated by proteins; toxins by anti-toxins; acids by alkalies; benzoic acid by glycocoll, etc. The extent of the disintoxication depends on the activity of the metabolic processes which are concerned, or on the amount of neutralizing substance present in the body.

Excretion of drugs. The main channels of excretion are the kidneys and bowels, and with volatile drugs the lungs. The sweat and for that matter other secretions play a comparatively minor part. The relative importance of different channels varies for each drug. The excretion is proportionate to the circulation of the blood and may be increased by factors which stimulate it. The excretion of certain drugs is limited by their being in the body in the form of combinations; the elimination of these is favoured by substances which displace them in the compounds (excretion of iodides is increased by giving chlorides).

Certain drugs are excreted by sweat, *e.g.*, iodides, bromides, borates, phenol, salicylates, antipyrin, methylene blue, arsenic and mercury. The quantities thus got rid of are too small to be of any significance from the point of view of elimination, but they help to explain certain skin conditions which accompany their administration. Excretion by saliva is limited to iodides, potassium, ammonium, mercury, lead, menthol, guaicol and some alkaloids (morphine and quinine). The excretion generally begins within 20 minutes and lasts for nine hours.

Passage into cerebro-spinal fluid. Organic substances get into the cerebro-spinal fluid to a very small extent; iodides and bromides are present in traces. Many organic substances pass in more freely, thus alcohol, chloroform, acetone and methanamine occur constantly in about one-third the concentration of the serum; aniline dyes are not generally found in the cerebro-spinal fluid, or in the gray matter of the brain after intravenous injection; those which are liposoluble are found in the gray matter. The passage into the cerebro-spinal fluid varies

with the species of animal; thus picric acid penetrates in dogs, cats and guinea pigs, but not in rabbits.

Passage to foetus. Chloroform, ether, alcohol, chloral, ethyl bromide, scopolamine, quinine, atropine, morphine, arsenic, mercury, potassium iodide, potassium bromide, carbon monoxide, salicylic and benzoic acid, phloridzin, nitrates, urea, methylene blue, pass into the foetus if given to mother. The placenta acts as an ultra-filter towards colloids. The colloidal dyes and proteins do not pass into the foetal circulation.

CHAPTER II

CONDITIONS MODIFYING THE ACTION OF DRUGS

The action of drugs in the body is dependent on several factors:—

1. The first thing to be considered is the dosage. By this is meant the quantity of a drug required to produce action either immediately or after repetition. The largest quantity which can be given without untoward effects is called the *Maximum dose*. Young persons require smaller doses than older ones, since younger tissues react more readily and also because the weight is less. In children the dose is usually given according to age.

Many practical rules have been devised for calculating the doses for children when the adult dose is known.

(a) Young's rule:
$$\text{adult dose} \times \frac{\text{age}}{\text{age} + 12}$$

(b) Cowling's rule:
$$\frac{\text{adult dose} \times \text{age at next birth day}}{24}$$

If prescribing 24 doses all that is required is to multiply the adult dose with age of the child in years.

(c) Bush's rule. Multiply the age by 5, this gives the percentage of the adult dose.

In this connection Clark has formulated a method of dosage for a person of known weight—
$$\frac{\text{adult dose} \times \text{weight of person in pounds}}{150}$$
150 lb. is taken as average weight of an adult person. This method, though useful, is not always feasible as it is impossible to weigh a patient lying in bed. A rough estimate of the probable weight can, however, be made.

A single dose may be given or divided doses may be administered ($\frac{1}{4}$ gr. calomel every half hour till 2 or 4 grains are taken). Repeated doses may be given (1) to have effect just at the time of administration, or (2) to have continuous effect (digitalis for disordered heart).

Cumulative action. The repetition of a drug produces greater effects than the first dose. Toxic effects may be produced by repeated administration of drugs. This may be due to (1) the amount of drug excreted being less than the amount absorbed. Such drugs are called cumulative poisons, *e.g.*, digitalis, arsenic, mercury, lead, etc.; (2) it may also occur when the excretion is decreased or suddenly stopped for some reason (nephritis), or (3) a sudden solution and absorption of a sparingly soluble drug owing to some change in intestinal content. Successive doses of the drug may remain unabsorbed in the alimentary canal, in the muscle or subcutaneous tissue, to be finally taken into the system when the conditions are more favourable for absorption. It sometimes happens that effects are more easily reproduced after they have been once induced. This is particularly the case with drugs acting on the central nervous system. Susceptibility to strychnine increases with its administration and is said to be due to the central nervous system becoming educated to the stimulating actions and responding to them more.

Pushing a drug to its *physiological limit* means to give the remedy in increasing doses till toxic symptoms appear.

1. **Dosage and effect.** A drug may have different effects according to the dose in which it is given, *e.g.*, ammonium carbonate is an expectorant in 3—10 gr. doses and an emetic when 30 gr. are given. It should be remembered that body weight has an important bearing on dosage and in prescribing drugs this should always be taken into consideration. In pharmacological experimentation, it is customary to estimate dosage in proportion to weight and within certain limits, this should be a good method for human beings. Smaller persons require less than larger persons. The required dose of most drugs is nearly proportionate to the body weight.

2. **Habit** usually lessens the effect of drugs to some extent; persons habitually using morphine or opium need bigger doses of these drugs; persons taking large doses of alcohol need larger doses of hypnotic and anaesthetic drugs. In a few cases the reaction is greater after continued use, as in case of the purgative *cascara sagrada*. In the case of habit-producing

drugs tolerance may be largely psychic. The nervous centres learn to modify the reactions so as to adapt them to drug environments. When this environment is abruptly altered by withdrawal of the drug, there is generally extreme discomfort, resulting in craving and great nervousness, constituting abstinence symptoms. Functional habituation, when acquired for a particular drug, may hold also for other drugs having a similar action.

3. **Sex.** Women are more delicate and lighter than men and need four-fifths of the dose of men. Idiosyncrasy occurs more often in the female sex; during the menstrual period certain drugs are not advisable (*e.g.*, quinine causes hæmorrhage). Pregnancy and lactation should also be taken into consideration as some drugs are excreted in milk, while others have action on the gravid uterus.

4. **Time of administration.** This is of importance, *e.g.*, saline cathartics act most rapidly on an empty stomach after a period of fasting, so they are usually given in the morning before breakfast. The more slowly-acting purgatives are given at bed time and half an hour before meals. Irritant drugs, such as arsenic or iron, are best given after meals, when they become well diluted with the stomach contents and come in contact with the stomach wall in lesser concentration and do not irritate it; quinine sulphate is best given $1\frac{1}{2}$ to 2 hours after meals, because it is more quickly absorbed when the contents of the stomach are acid and besides it is less liable to disturb digestion at this time; digitalis preparations are best given by themselves on an empty stomach. Soporific drugs are most effective at the natural time of sleep; they may be without effect if the patient is not in bed and is up and about. Sodium bicarbonate is given on an empty stomach because, if given during the digestive period, it neutralizes the hydrochloric acid of the gastric juice.

Relationship between the time of administration of a drug and meal-time may influence not only the rate of absorption, but also may modify its action. Given on a full stomach, the absorption is slower than when given some hours after meals;

if local action is desired on the stomach, the drug should be given before meals.

5. Climate in which a person lives renders him more or less susceptible to certain remedies, *e.g.*, alcohol is better borne in cold climates. The temperament of an individual is an important factor; phlegmatic dark-skinned people react to drugs less readily than blondes and nervous patients, especially in respect of drugs which act on the nervous system.

6. The preparation employed is also a matter of importance; whenever possible, a standard preparation should be used (pure alkaloid).

7. **Idiosyncrasy and susceptibility.** Drugs may exert an unexpected effect either by having an unusual action or failing to produce ordinary action. The term idiosyncrasy is applied to peculiar, exceptional reactions to the effect of drugs. It is a condition of increased susceptibility to a remedy. There may be quantitative hyper-susceptibility to ordinary actions of drugs, so that side actions, which are ordinarily negligible, become greatly accentuated. Neurotic individuals are subject to psychic exaggeration or modification of drug effects through fright, excitement or suggestion. They are frequent causes of disappointment both to the physician and the patient and may give rise to excessive action from what has been thought to be a moderate dose.

Allergic hyper-susceptibility is a type of idiosyncrasy in which the patient reacts to special substances, food or drugs, by irritant oedema and spasm of smooth muscles, urticaria, bronchial asthma and collapse. It is generally hereditary but not congenital, *i.e.*, it may manifest itself in later life. It resides in the tissues so that it cannot be transferred to the blood serum. It can be induced in excised tissues by treatment with colloidal precipitants. Some people develop a rash or even very serious symptoms after eating strawberries, others after taking certain kinds of fish. Sometimes all members of a family show such an idiosyncrasy to a special article of food or to a particular drug. Thus it has been reported that a minute amount of cocaine dropped into the eye or a few grains of quinine taken internally have produced very serious symptoms. The cause of this

condition is not quite clear. Slight alteration in the composition of tissues may cause similar conditions, *e.g.*, deficiency of calcium renders the whole autonomic nervous system more susceptible to the action of certain drugs. The variations in reactions of different animals or racial idiosyncrasy can be explained by difference in physiologic functions; for instance, cerebral reactions are usually predominant when the central nervous system is highly developed, while spinal reactions predominate in lower vertebrates. Rabbits are incapable of vomiting, therefore, they cannot be affected by emetics. Atropine quickens the heart in dogs but not in rabbits, because it paralyses the vagus which is not tonically active in this animal. The dog-fish is more or less resistant to nephrotoxic poison as it normally excretes urea and other metabolic products through the gastro-intestinal tract. Normal resistance may be due to destruction of the poison, *e.g.*, atropine by serum of rabbits. Differences of absorption and excretion also come into play. There are many factors, however, which cannot be satisfactorily explained. The resistance of the hedgehog to poisons like morphine, nicotine, atropine, cyanide and arsenites and not to strychnine, cannot however be explained. It should not be forgotten that abnormal reactions following the administration of drugs may rarely be due to the presence of impurities.

8. **Tolerance.** Some animals and men fail to react to drugs even when given in considerable doses and this phenomenon is known as tolerance which may be natural or acquired, *i.e.*, developed by repeated administration of a drug. Natural tolerance may be due to the power of the tissues to neutralise poisons. Thus carnivora can stand large amounts of acids owing to the production of ammonia in their tissues; chickens are immune to oxalic acid when given by mouth, because of the large amount of calcium in their intestines.

Acquired tolerance is the result of habituation to drugs. This may be functional (alcohol, caffeine, nicotine); or it may be due to diminished absorption (arsenic), to increased elimination (atropine in cats), to increased destruction of poison (morphine) or to production of antibodies (toxins). The tolerance

is usually limited, not absolute. Any condition which lowers the general resistance of the animal increases its susceptibility to the poison (frog in tepid water). Tolerance differs from immunity in that anti-toxins are said to be formed in the latter. Anti-toxin formation, however, is an instance of acquired tolerance. It was supposed to be confined to proteins, but it appears to exist also towards certain glucosides (toad-stool and snake venom). It does not occur with alkaloids. It has not been shown that any chemical substances except proteins produce anti-bodies.

9. Effect of disease and pathological conditions. Many pathological conditions modify drug action. The effect of drugs in disease may differ materially from that in health. Antipyretics reduce temperature in fever but not in health; bromides lessen nervous irritability more in epilepsy than in health; morphine in pain lessens sensitivity but has less effect in health; in malaria quinine is tolerated in much larger doses than in health; antimony compounds are tolerated better in kala-azar. Pathologic conditions may modify absorption and excretion. Suppression of urine, as in nephritis, may lead to toxic symptoms from drugs and in doses which are ordinarily harmless. Absorption of poisons is hastened immediately after hæmorrhage. Inflamed vessels react abnormally, epinephrine may produce dilatation and caffeine constriction of the vessels, in a rabbit's ear. Diseased intestines allow much more rapid diffusion of proteins, toxins and ferments than healthy intestines. The distribution of the drug in the body may differ in health and disease. Iodides and many dyes tend to accumulate in the necrotic areas of tuberculosis, tumours, etc. Diseased conditions may lessen absorption (*e.g.*, in diarrhoea) or increase it (*e.g.*, in corrosion or ulceration of gut); they may accelerate destruction of poison (alcohol produces less intoxication in pneumonia) or they may alter the effect entirely.

10. Synergism and antagonism. A drug exerts its usual activity much more easily if it is given with some other drug of the same class, and it is found that combination of two drugs having the same action will give a result which one alone will not produce, however large the dose might be. Such drugs are

called synergists or mutual helpers and the phenomenon is known as synergism. In some cases new actions develop by the reaction of drugs with each other, with the production of new compounds (acid renders the basic salts of bismuth soluble and toxic).

Synergism of drugs was responsible for combination therapy which had the idea of securing summation of the desirable effects of several drugs; the side actions usually do not increase and in some cases they are neutralised. Formerly this form of therapy was popular and shot-gun prescriptions were given with the idea that some at least of the many ingredients might attack the disease. Such indiscriminate empirical use of drugs, however, is not scientific and it is better to employ only a few drugs with known actions. More recently, the combination method has been tried with great success by Ehrlich in treatment of protozoal diseases, for this is the principle underlying chemotherapy. In combining several drugs having a similar action the dose of each should be correspondingly reduced.

The best examples of synergism are seen in the group of narcotics. In the case of alcohol, ether and chloroform the effect is simple summation, but in case of morphine and scopolamine there is considerable potentiation of effects. Again an injection of magnesium sulphate considerably helps the action of ether in the production of general anaesthesia. A mixture of purgatives, *e.g.*, calomel, jalap and colocynth, act better than a single purgative.

The potentiation may be produced by one drug modifying the penetration of the other into the cell, altering the chemical affinity or attacking the cell from a different point of view. Magnesium potentiates urethane, and ether potentiates chloral or morphine, by favouring their distribution in the central nervous system.

On the other hand, a drug may lose a part or all of its action because of some agent which has the opposite physiologic effect. Such opposing agents are called antagonists and the phenomenon is known as antagonism. There are examples of antagonistic substances being manufactured by the body itself (epinephrine and thyroxine). The antagonism between drugs and

poisons when this depends on the antagonistic innervation of certain organs is easy to understand (*i.e.*, vasodilators and vasoconstrictors). Much more difficult to understand is the antagonism by which one drug overcomes the effect of another in the same cell without the aid of physiological mechanism. This may be brought about in two ways:—

(1) By chemical changes or combination as in case of free acids and alkaline carbonates, oxalates and lime salts.

(2) By true antagonism, as in case of atropine and muscarine, which is of truly physiologic nature, for these two drugs have no chemical affinities for each other, but produce directly opposite effects on the same organic element. The action of potassium chloride and ammonium chloride on the yeast ferment invertin, gives a simple type of this antagonism, the first inhibiting and the latter favouring, and the two together in proper proportions leaving the activity unaltered. In other words, there is complete reciprocal antagonism. The possibility of this has been denied on the ground that while it is possible to bring about paralysis in a stimulated organism, it is not possible to bring about stimulation in a paralysed one. It must not be forgotten, however, that combination between poison and protoplasm is of a dissoluble nature, so that cells may be restored again and poison washed out from them if bathed with blood which is free from the poison. Reciprocal antagonism between calcium and magnesium and sodium and potassium is clearly demonstrated in living organism, for the tissues can maintain their normal function, particularly their normal excitability, only when these kations are present in their correct relative proportions.

Antagonistic drugs may act, (*a*) on the same structures, *e.g.*, bromide and strychnine on the spinal cord; caffeine and alcohol on psychic and motor centres in the cerebrum; pilocarpine and atropine on the vagus nerve-endings; (*b*) on different structures, *e.g.*, digitalis slows the heart by stimulating the vagus centre, atropine prevents this by depressing the vagus nerve endings. Adrenalin contracts vessels by stimulating the vasoconstrictor fibres while nitrites relax them by acting on the muscle fibres.

CHAPTER III

MODES OF ADMINISTRATION

By mode of administration is meant the way in which a remedy is to be used. Remedies are given to obtain either direct local action, a remote local action, a systemic or general action.

(1) **The direct local action** of a drug is exerted at the place at which a drug is applied, *e.g.*, skin, nose, urethra, etc. Locally, drugs may act by protection, irritation, or depression of sensory nerve endings or other tissues. Many drugs act locally only, others like strychnine, exert little or no effect at the point of application, but exert a marked general effect. Local remedies may or may not require to be absorbed, *e.g.*, bismuth subnitrate for an irritated stomach, talc powder for skin which is chafed.

(2) **Remote action.** Remote or indirect action is an action elicited on organs away from the site of application. Such action of drugs may appear (a) after its absorption into the circulation, *e.g.*, of strychnine on the spinal cord; pilocarpine on the secretion; (b) without actual absorption, *e.g.*, irritation of the skin, blisters or cold applications influence the rate of the heart, indirectly through the central nervous system. Sometimes the effect of a drug is manifested as it is being excreted, *e.g.*, irritation of the bowels and kidneys by perchloride of mercury as it is passed out *via* the colon and the urine; anti-septic action of urotropine as it is eliminated in the urine.

(3) **The general action** is one that cannot be fixed in any particular tissue, *i.e.*, the action of many tonics and sedatives.

The effect of a remedy depends largely on the way in which it is given, *i.e.*, adrenaline given by mouth has a local action on the stomach only, while if given hypodermically or intravenously it produces an enormous rise of blood pressure. A dose of saponin by the mouth is perfectly harmless, but it gives rise to poisonous symptoms if given under the skin. Some tissues and organs absorb much more rapidly than others,

therefore, larger quantities of the drugs, pass through them into the blood in a given time. For instance, if a poison which is absorbed slowly, be rapidly excreted, so little of it will exist in the blood and tissues at a time that hardly any action is produced; while if it is rapidly absorbed by some other method of administration, even a small dose will exert some action before it is excreted, *e.g.*, potassium salts given by the mouth are not poisonous in large quantities, but when given hypodermically or intravenously they produce toxic effects to certain organs.

The channel by which a drug is introduced into the body or the place to which it is applied, must necessarily vary with the object to be secured, *i.e.*, whether the action is to be purely local or general; whether rapidity of absorption is desired or whether there is any necessity of avoiding irritation to certain organs, etc.

1. **Local application.** Locally, drugs may be used to protect surfaces, for producing reflex effects, for antiseptic or stimulant purposes.

On the skin, drugs may be applied in various vehicles. If it is desired the drug should penetrate deeply or be absorbed it should be mixed with animal or vegetable fats. The reason is that although the lower layers of skin absorb readily, the stratum corneum of the epidermis is non-permeable to most substances. The absorption takes place through the glandular structures which are filled with fatty matter. Increased vascularity of the skin favours absorption by carrying away quickly the absorbed drug. Where local effect alone is desired, mineral fats (vaseline) may be used. Oils and ointments delay the absorption of fat-soluble substances, such as phenol, mustard oil, etc.

Local application to the skin has to be used for producing general effects in those cases where the stomach must be avoided and the subcutaneous method is not practicable, *e.g.*,unction of mercury. The objection to this method is that (1) absorption is uncertain and consequently exact dosage is impossible, (2) the absorption is greatest where the skin is

most delicate (axilla, loins, inner surface of the extremities). Absorption is aided by rubbing.

Watery solutions as a rule are not absorbed from the skin but when the solutions are brought in intimate contact, certain salts may be absorbed. Skin is capable of absorbing sulphuretted hydrogen and other gases. Application of watery solutions to the abraded skin or open wounds is, however, quite a different matter. Absorption under such conditions, takes place readily and the rate of absorption is practically similar to that obtained by subcutaneous injections. Chronic and callous ulcerations with defective circulation are, however, poor absorbing surfaces.

Cataphoresis or ionic medication. Many drugs, which are not ordinarily absorbed through the skin, may be made to do so by means of an electric current. This method is known as ionisation. Convulsions have been produced by driving strychnine into the tissues by ionisation. For further details of the method, see the chapter on physiotherapy.

On mucous membranes: Drugs can be applied locally to surfaces other than skin, *e.g.*, mucous membranes. The conjunctiva absorbs readily, so that apart from local action, a systemic effect of drugs may, sometimes, be produced, *e.g.*, atropine. A few milligrams of apomorphine in the conjunctival sac of a dog produce vomiting. The vagina absorbs freely and clinical poisoning may be produced by giving the drug in the form of douches. The uterine cavity also provides a very good absorbent surface. The urethra absorbs readily and frequent poisoning has occurred from application of local anæsthetics. The urinary bladder absorbs poorly; drugs like strychnine, apomorphine, morphine, etc., are quite harmless when given by this way. The ureter and renal pelvis absorb fairly well.

Sprays are finely atomised solutions and are inhaled for their local action on the mucous membrane of the nose, pharynx and larynx. They must not be too irritant. To reach the lower air passages they should be deeply inhaled with the nostrils closed, the mouth widely opened and the tongue slightly protruded.

Insufflation. Powders are frequently blown on to a surface, *e.g.*, boric acid into the ear or relatively inaccessible parts.

Inhalations. This method is used for gaseous medicines such as anæsthetics, oxygen, etc. The effect depends on the concentration of the gas and the time during which it is administered. The action is most rapid as they reach the blood stream quickly. The capillary surface of the lungs, which is only separated from the alveolar air by a single layer of flattened epithelial cells, is wonderfully adapted for absorption of volatile substances into the blood. The chief advantage of this route of administration is the possibility of controlling the amount of drug at any desired time. The effect also disappears quickly after the drug is discontinued.

The lungs also absorb fluids and dissolve substances rapidly if these are introduced through the trachea. A continuous stream of warm water given into the trachea of a horse, at the rate of 6 litres per hour was absorbed ; no trace of water being found, though the animal died of direct injury to the lung tissue. Rabbits can receive 30 to 40 c.cm. of fluid into the trachea. If the fluid is injected more rapidly than it is absorbed it fills up the alveoli and produces asphyxia. This route of administration is, however, not used in therapeutics on account of the danger of asphyxia.

Inhalations for local action. These can be effectively employed by evaporating the substance with steam, either by placing it on boiling water and inhaling it through a funnel, or by the steam atomizer. The steam gets condensed on the surface of the mucous membrane and the drug is deposited at that area. Even with deep inhalations the vapour does not go beyond the larger bronchi. The respiratory movements, however, tend to distribute the material widely through the lungs. In many affections of the nasal and upper respiratory passages this method is very commonly used.

Intratracheal injections. Small quantities 2 or 3 c.cm. of oily solutions (*e.g.*, menthol) may be injected directly into trachea through the glottis. They then are distributed by respiration similarly to those by sprays and steams. The advantage is not apparent.

2. Oral and rectal administration. Oral administration is the most ancient method and is still the method of choice with most drugs. Drugs whose general action is desired after absorption are generally given by this way, but sometimes drugs may be given for their local effect by this route also (*e.g.*, bismuth and emetics for their action on the stomach, vegetable purgatives on the intestines).

Some drugs give rise to disturbances of digestion when given by the mouth. This can be avoided by giving them

in the form of pills coated with keratin, in capsules or cachets so that they will not get dissolved in the stomach, or they may be given when the stomach is full so that they are diluted. Absorption mainly takes place from the small intestines.

Rectal administration may be used to avoid the action of a drug on the stomach and the small intestine. The rectum, on account of its profuse vascularity and venous plexuses, is a very good absorbing surface for many soluble substances so that effects are often more prompt and more marked than with the oral method. Absorbed substances also do not pass through the liver where they are liable to be destroyed. The drug is given in the form of an enema or suppository. Enemata when given for absorption should be as small as possible (2 ounces) and not irritant. The rectum should be washed out with warm water before they are given. About twice the dose given by the mouth is necessary to produce the usual effects.

The rectal administration of drugs has been practised since the time of Galen and although its utility is limited, it still occupies a very large place in therapeutics. As many drugs are fairly well absorbed from the rectal mucous membrane, there is a growing idea that this route of administration may be resorted to in supplying nutriment to the system whenever occasion demands it.

Rectal feeding. The use of nutrient enemata or suppositories containing food materials is based on the assumption that absorption takes place from the rectum and the large bowel. The absorption of foodstuffs from the rectum is, however, very limited. Physiologically, the rectal mucous membrane is unsuited for the purpose of digestion and absorption of nutrient material. The main digestion of food, as is well known, takes place in the small intestines. The pancreatic juice furnishes powerful ferments which digest starch (amylase), fats (lipase) and proteins (trypsin). The bile renders important assistance in the digestion of fats. The secretion of the mucous membrane of the intestines (succus entericus) also possesses an important digestive function through its ferment 'erepsin.' After the digestion is completed, absorption takes place through the highly specialised epithelium of the villi of the intestinal mucosa. Practically the whole process of digestion and absorption is completed in the small intestines before the material is transferred through the ilio-cæcal valve into the large

intestines. In the large intestines absorption of water chiefly takes place. 'Erepsin' is the only ferment present which can break down proteoses and peptones only into the simpler amino-acids. The villi are widely different and are unsuited to the absorption of nutrient material.

The bacterial contents of the large intestines may play a part in digesting certain materials which are resistant to the action of the digestive juices in the small intestines, e.g., cellulose, but this digestion is very insignificant in human beings.

Absorption of proteins. Some observers have stated as a result of comparative study of the nitrogenous metabolism in patients on rectal feeding, that quite large amounts of protein are absorbed. Recent observations have, however, demonstrated that this statement was based on fallacious experimentation and cannot be taken at its face value. Boyd has shown that nitrogenous equilibrium could not be obtained during rectal feeding even in those who were accustomed to a diet poor in nitrogen. Laidlaw and Ryffel estimated the nitrogenous output in a case of rectal feeding during coma, and found that it was approximately equal to that obtained in the later stages of fasting, indicating that protein absorption was not taking place. The nutrient enemata they employed, consisted of the white of nine eggs, 6 ounces of raw starch and 24 ounces of peptonised milk in the day. Langdon Brown has carried out a number of experiments by giving nutrient enemata consisting of milk, plasmon, dextrose, sodium bicarbonate and liquor pancreaticus. He estimated the nitrogenous output in the urine, as this is a more accurate criterion of the absorption of nitrogenous material from the bowel than the loss of nitrogen from the rectal washings, which method was employed by previous workers. It was found that the nitrogenous metabolism was hardly affected.

Absorption of carbohydrates. Normally, carbohydrates are absorbed by the bowel as dextrose, and of all the foodstuffs, this appears to be very well utilised in rectal administration. That dextrose is definitely absorbed from the bowel is proved by the fact that the respiratory quotient was raised and that ketosis could be definitely abolished. Mutch and Ryffel advise 6 per cent. of dextrose in 15 ounces of tap water, six hourly, with daily irrigation of the bowel four hours after the last dose. Different observers have claimed that nearly 67 to 100 per cent. of the carbohydrates are absorbed.

Absorption of fats. As is well known, fats are never absorbed *in toto* but are first broken up into glycerin and fatty acids through the agency of an enzyme 'lipase.' This ferment is not present in the large intestines but is supplied by the pancreatic juice. Bacterial decomposition may, under exceptional circumstances, break up the fats but this is not of much significance. Even if the pancreatic ferment is provided by the addition of liquor pancreaticus, absorption of fats is not satisfactory. The fat in the yolk of the egg is considered to be better

absorbed than other forms of fat and has been widely employed. Eggs are, however, not absorbed and most of them are thrown out and add to the nursing difficulties without any advantage to the patient. Though the earlier reports indicate that partial absorption of fats takes place, recent observations by Langdon Brown definitely negative the suggestion. Practically no fat is absorbed from nutrient enemata by the large bowel.

Absorption of salt and water. It is agreed by all physiologists that salts and water are freely absorbed from the large intestines and the advantages claimed for rectal feeding are probably due to these ingredients. It is well known that the body can stand deprivation of food for a considerable time if these articles are supplied. W. Pashev advocated the administration of 10 oz. enemata of plain water at a temperature of 100°F. every four or six hours. Sharkey has used $\frac{1}{2}$ pint of saline four times in each 24 hours with satisfactory results.

It will, therefore, be seen that the principle of rectal feeding is physiologically not very sound. It is only a poor substitute for oral feeding, as absorption from the small intestine is completely cut off. It has been claimed that the larger enemata will get through the ileo-cæcal valve, and be absorbed in the small intestine. Church noted in a case of duodenal fistula that some quantity of a soap and water enema reappeared through the opening. This regurgitation of rectal enemata is such an exceptional circumstance that no reliance can be placed on it. We have, therefore, to depend on the capacity of the rectal mucous membrane to absorb the foodstuffs. As the large intestine is the principal place for the absorption of water, it is essential to supply the nourishment desired, in fluid form. But even in this form, its utility is limited. If any protein is absorbed from the ordinary nutrient enemata, the amount is so small as to make it hardly worth while to subject patients to so much discomfort for so small an advantage. A gain in weight has been claimed as evidence of their value, but this has been observed with rectal salines alone. Eggs and other fatty foods have been shown not to be absorbed. If dextrose is added, ketosis can be definitely stopped and therefore carbohydrates in such forms are the only foodstuff indicated.

It appears possible that better results might be obtained if the proteins are completely broken down into amino-acids, the form in which absorption normally occurs. Rendle Short and Bywaters have found, by allowing pancreatic extract to act on milk for twenty-four hours and using the digested material as an enema, that decidedly better absorption takes place. This plan is worthy of trial in exceptional cases, though its value has not been established beyond doubt.

Disadvantages of rectal feeding. It is true that water, salts and dextrose can be absorbed from the large bowel in sufficient quantities to tide the patient over periods of difficulty and may avoid ketosis when

for some reason or other, the patient cannot take anything by the mouth. There are, however, certain disadvantages which should be borne in mind. Apart from the inconvenience and difficulty caused in keeping the patient in a clean condition, there are certain symptoms which require attention. Excessive thirst, persistent vomiting, reflex secretion of gastric juice, parotitis due to ascending infection of the salivary ducts, etc., are some of the unpleasant complications. These can be avoided to a large extent if proper nursing facilities are available.

3. Administration of drugs by injection. This method is of comparatively recent origin, but its use is being more and more extended every year.

Irritant drugs should not be given by injection into the tissues, as this may cause great pain and swelling and sometimes suppuration, even when all precautions regarding sterilisation are taken, *e.g.*, turpentine, and digitalis glucoside. The advantages of the injection method are :—

(1) Certainty of action, as all the drug gets into the tissues and therefore the dose is definite.

(2) Rapidity of action, as the drug quickly reaches the circulation.

(3) When administration by the mouth is not possible, as when the patient cannot swallow (unconsciousness, drunkenness, etc.) or when the alimentary tract cannot tolerate or absorb drugs (uncontrollable vomiting and diarrhoea).

The disadvantages are :—(1) Abscess may form at the site of injection if precautions are not taken, (2) the drug may be injected by mistake into a vein with disastrous results, (3) the drug may be injected into a nerve giving rise to excruciating pain or paralysis (*e.g.*, quinine). All these can be avoided if sufficient care is taken.

Subcutaneous or hypodermic injection. In this method, the drug is given into the subcutaneous tissues by means of a hollow needle. All preparations meant for subcutaneous injection should be in liquid form, solutions or colloidal suspensions should be capable of complete absorption, for otherwise they will set up irritation. The quantity injected should not be too large (under 5 c.cm). Large quantities of saline are sometimes injected into the loose tissue about the

breast, axilla, abdomen or into the back below the scapulæ, the liquid being allowed to run in slowly. Care should be taken that the fluid is isotonic or nearly so with blood, for otherwise it will not be absorbed and pressure on vessels may cause gangrene or abscess.

Subdural injections. These are used when the drug is required to act directly on the spinal cord and nerve roots, *e.g.*, spinal anaesthesia. Colloidal drugs, which do not readily permeate the nervous tissue from the blood, are also given by this way, *e.g.*, tetanus antitoxin. The technique is that of lumbar puncture, some cerebro-spinal fluid being withdrawn before the injection is made. The procedure is dangerous if the drug produces local irritation or is conveyed to the medulla and thus acts on the vital centres. The absorption of drugs from subdural injection into the general circulation is doubtful, as even drugs like adrenalin, nicotine, etc., do not produce their general effects. During intra-spinal administration the patient should keep in a rigidly fixed position, otherwise the movement of the patient may break the needle, which is a very serious matter. Sub-arachnoid irrigation has been experimentally tried.

Intracranial administration is sometimes given in urgent cases, and drugs like salvarsan have been given through a trephine hole in the skull. Special training and technique is necessary for both these.

Sub-lingual and sub-nasal administration. Injections under the mucous membrane in these regions are rapidly absorbed, being as effective as intravenous injections. Some drugs like nitroglycerin can be given effectively by holding a tablet under the tongue.

Intrapericardial injections. Solutions are rapidly absorbed from the pericardium into the heart muscle. It has been suggested that this method may be used for epinephrine resuscitation in extreme cases. Intracardiac injection is now employed for this purpose.

Intraperitoneal and intrapleural injections. These are used in animal experimentation, but rarely in man. The pleura absorbs from the parietal and pulmonary surfaces, but the absorption is less from the peritoneum. In both cases the absorption occurs by the blood stream rather than by the lymph. Gravity plays a part, the absorption being little from the pelvis.

Intrahepatic injections. These are used instead of intravenous injections in small animals, such as frogs, turtles and rats, but are not recommended in man.

Intramuscular injections. These are made by thrusting the needle through the skin deep into the substance of the gluteal or other muscles. The injections do not remain confined to the muscle, but rupture the muscle bundles and spread

along the nearest fasciæ, thus greatly increasing the absorbing surface. The absorption, therefore, is more rapid than with subcutaneous administration and in view of the fact that sensory nerve-endings are fewer than in the skin, the pain is less evident. The tendency to abscess formation is also much less. Intramuscular injections are particularly useful when relatively insoluble powders suspended in oil have to be administered. These establish a depot for gradual absorption and continued action, *e.g.*, mercury salicylate in the treatment of syphilis. Suspension of metallic salts in oil are best injected intramuscularly as they are not absorbed from the subcutaneous tissues.

Intravenous administration. During recent years, the practice of intravenous medication has come to the forefront. Twenty years ago, medical men would not willingly undertake the injection of a drug into a vein. Now-a-days, however, the popularity of the method has increased and the modern physician performs this operation with alacrity and skill. Attempt is made to give almost every drug by this route on the assumption that intravenous medication produces a more powerful therapeutic effects than administration of drugs by other channels. This misconception has assumed such proportions that it is both timely and important to consider the real merits and limitations of this form of therapy.

Evolution of the method. The idea of intravenous medication was first started in 1655 when Christopher Wren experimented on dogs and showed that drugs could be given into a vein without ill-effects. A year later the first intravenous injection was given in man. Later, others tried this method of medication with a variety of drugs, but the haphazard ways of experimentation damaged the reputation of this procedure. Bacelli (1890) saved the method from adverse criticisms by his successful treatment of malaria with intravenous quinine. He advocated the method as a routine treatment on the assumption that the drug was brought immediately into contact with the parasites whereas when given by the oral route the time required for absorption would necessarily delay action. His support of intravenous therapy, at a time when the method was almost being discarded as dangerous, had a very steadying effect on the minds of medical men and since then, the method has gradually gained in popularity. Crede (1902) tried colloidal metals in the treatment of

septicaemia, but his attempts were not successful, as several fatalities occurred. The discovery of salvarsan in the beginning of this century and its safe intravenous use put intravenous therapy on a sound and stable basis (1910). The demonstration of the relative harmlessness of intravenous salvarsan injection came as a great relief to the physician who could thus treat syphilis without giving the patient the excruciating pain attending on intramuscular injections.

Physiological considerations. A knowledge of the inherent properties of the blood is essential in order to have a closer conception of this method of administration. A brief reference to the physiological considerations will not, therefore, be out of place here.

The blood is the chief medium through which any drug introduced by any channel will be distributed to different parts of the body. It is a special fluid, having the function of carrying nutrition and oxygen to all the tissues and eliminating the waste products that accumulate as a result of metabolism. It also takes certain chemical substances that are formed by physiological activity of an organ to other organs, thus regulating and co-ordinating the functions of different organs of the body. The total volume of blood has been estimated approximately to be $1/13$ of the body weight. The erythrocytes form about 50 per cent. of the total mass and consist of two parts, stroma and haemoglobin in a state of loose combination. This combination may be broken up by various means such as dilution of the blood with water, addition of ether, or bringing it into contact with haemolysins. Laking of the blood by dilution with water makes the consideration of the osmotic relations of the erythrocytes an important study in intravenous injection. If the osmotic pressure of the blood plasma is reduced by diluting with water, the corpuscles in order to maintain the balance, break up liberating their haemoglobin. If a strong solution of common salt is added to the blood so as to make the osmotic pressure of the plasma higher than that of the erythrocytes, water will pass from the corpuscles to the plasma to maintain the equilibrium and the corpuscles will be crenated. The osmotic pressure of both the plasma and the corpuscle will, therefore, remain unaffected between these two extremes and this point is reached by a solution containing 0.9 per cent. of sodium chloride, for mammalian blood. The erythrocytes are impermeable to most neutral salts and, therefore, it is possible to make normal solutions with sodium sulphate or with cane sugar by making the solution isotonic with 0.9 per cent. sodium chloride. Certain substances like alcohol, ether, etc., however, can permeate through the corpuscles. The blood corpuscles resemble most animal and vegetable cells in permitting the passage of those substances that are soluble in fat and fat-like bodies, e.g., lecithin and cholestrin.

(a) **Specific gravity of blood.** The specific gravity of the blood in the male sex varies between 1056 and 1058 and in the female sex from

1054 to 1056. The question of specific gravity becomes important when large quantities of saline are infused intravenously as in cases of cholera. If the specific gravity of the blood is high enough, as it is in this disease, very large quantities of saline can be injected without any untoward effects. When the specific gravity is within normal limits, administration of large quantities of saline is liable to produce oedema of lungs and death.

(b) **Hydrogen-ion-concentration.** The hydrogen-ion-concentration of the blood is another important consideration in intravenous therapy. The blood, as is well known, is alkaline to litmus. The pH of this fluid depends mainly upon the ratio between the concentration of carbon dioxide and bicarbonates in the blood, and these two are so balanced that the pH is just on the alkaline side of neutrality. This balance may be expressed as an equation: $H \text{ (hydrogen-ion-concentration)} = K \cdot \frac{H_2CO_3}{NaHCO_3}$, where K is a constant. An addition of a trace of acid or alkali will disturb the balance by increasing or decreasing its numerator or denominator and make the pH move towards the acid or alkaline side of neutrality. The tissues and especially the higher centres in the medulla are extremely sensitive to the slightest changes in the hydrogen-ion-concentration of the blood, and any change in the relative proportions of H and OH ions which will take the pH of the blood to the acid side of neutrality will be met with rapid fatal results. Under ordinary conditions, therefore, intravenous injection of any acid solution would have been impossible. The blood, however, contains certain substances called 'buffers' which play an important part in maintaining the pH of the blood at a constant level. The mechanism by which the neutrality of the blood is maintained is described in detail in chapter on acidosis and alkalosis.

The balance of pH is so delicately maintained, that ordinary injection of drugs which are distinctly acid or alkaline produce no permanent change in the reaction of the blood. If, however, the rate of injection is rapid, the buffers present may not be able to keep the balance intact.

(c) **Volume of the blood.** The volume of the blood is another important subject for detailed study in connection with intravenous therapy. It is a well-known fact that the blood volume remains fairly constant despite influences which tend to alter it. After a severe hæmorrhage, the volume of the blood is made up by gradual imbibition of fluid from the tissues. Again when large quantities of saline solutions are injected into the circulation, the total blood volume does not alter permanently. In animals, about 100 to 200 c.cm. of normal saline infused slowly do not produce a rise in arterial pressure proportionate to the quantity injected. The fluid, therefore, must be accommodated either inside or outside the vascular system. There may be dilatation of the arterioles and capillaries to make room for the extra

volume of fluid or the fluid may pass out of the circulation into the tissues as lymph. Both factors appear to operate simultaneously. Immediately after such a transfusion an increased fullness in the vessels of the mucous membrane and retina can be observed. The fluid portions of the blood, however, rapidly pass from the blood vessels to the tissues giving rise to oedema, if the quantity of the fluid transfused is very large. This oedema might set in in such vital organs as the lungs and may produce serious respiratory distress or even death.

(d) **Air-embolism.** The question of the entry of air into the circulation may be briefly reviewed here. It is a matter of common observation in laboratories that small quantities of air introduced into the circulation do not have any deleterious effect on an animal. On the other hand, injection of large quantities of air is the quickest and surest method of killing an animal; 5 c.cm. of air suddenly introduced into the vein of a rabbit will produce fatal results within 2 or 3 minutes. If, however, the air is introduced slowly the animal does not die. If 5 to 10 c.cm. of air are injected abruptly into the vein of a cat, an immediate fall in blood pressure to zero is produced. The churning of blood and air in the heart produces froth, and sudden heart failure may occur due to very small quantities of blood entering the coronary arteries with consequent impairment of the nutrition of the heart. It must be realised, however, that in order to produce such result in man, the quantity of air introduced must be very large. Five to 10 c.cm. of air, even when introduced suddenly, will be rapidly absorbed by the blood and will produce no deleterious effects whatsoever.

Choice of drugs for injection. The selection of the salt to be given when several salts of an alkaloid are available should depend upon the solubility of the salt and its rate of diffusibility. Generally, the hydrochlorides are more soluble and more diffusible than the sulphates because of the smaller size of their molecules. Another point in favour of hydrochlorides is that HCl combines with the calcium of the blood, forming calcium chloride which is soluble. The calcium content of the blood will, therefore, not be affected. If a sulphate is given, the insoluble calcium sulphate which is produced will be precipitated and will deprive the heart of its proper calcium requirements. The chemical changes, such as these occurring in the blood, however, are so insignificant with ordinary injections that their effects are negligible in view of the large volume of the blood in circulation.

Some salts such as the pentavalent compounds of antimony produce a precipitate in the blood. This precipitate may

produce respiratory distress but the symptoms pass off rapidly and generally produce no untoward effects. Substances like salvarsan are not soluble in neutral watery solutions and therefore the blood cannot hold them in complete solution. They circulate in the blood in a semi-colloidal state.

Indications. The following are some of the chief indications for the administration of drugs by the intravenous route.

1. As an emergency measure when rapidity of action is desirable. A few examples may be given to illustrate the point:—(a) For combating acidosis in the body, *e.g.*, in diabetic coma, the intravenous infusion of saline, sodium bicarbonate, insulin, etc., may save the patient's life. (b) In severe forms of tetany, intravenous injections of calcium may prevent death. (c) In auricular fibrillation with impending death, an intravenous injection of strophanthin may act like a charm. (d) In malignant malaria, intravenous administration of quinine produces rapid curative effects. (e) Neglected and severe cases of diphtheria often demand the intravenous use of antitoxin, and sometimes respond to it favourably.

2. When greater intensity of action is desired than can be secured by other methods of administration. Arsenicals are given in syphilis by this route to produce an effective concentration in the blood. Antitetanic, antimentingococcic and antistreptococcic sera (especially for scarlet fever) are sometimes given intravenously to produce stronger action than can be obtained when given subcutaneously. Non-specific proteins, when used to induce protein shock, are best given into the vein, *e.g.*, typhoid vaccine in chronic arthritis.

3. To secure direct action on the infecting organisms within the blood stream, *e.g.*, quinine in malignant malaria, mercurochrome 220 soluble, gentian violet and colloidal metals in septicaemia.

4. To avoid irritation and destruction of tissue likely to be produced by drugs, such as arsenicals and antimonials, when given by other routes.

5. When the volume of the fluid is large it is better to give it intravenously than intramuscularly or subcutaneously, *e.g.* injections of saline in cholera. Though large quantities

of saline can be given under the breast and in the loose areolar tissues of the axilla, the procedure is very painful and should be avoided as far as possible.

Advantages over other modes of administration. 1. Precision of dosage. This can only be attained by injecting a drug straight into the blood stream. There is no certainty what amount of a drug administered orally is going to be absorbed finally into the circulation.

2. Absence of gastro-intestinal irritation: Arsenicals and antimonials cannot be given by the mouth.

3. Stability of the drug, *e.g.*, adrenaline and many hormones are rendered inert when given by the oral route.

4. Prompt action.

5. Avoiding irritation or destruction of tissue when given by subcutaneous or intramuscular method. •

Disadvantages and contra-indications. Intravenous medication* should not be resorted to if a drug can be effectively given by any of the other routes, as there are many risks attached to this form of medication. There is a growing tendency on the part of medical practitioners to resort to intravenous injections when the utility of this method is doubtful. This is to be strongly deprecated. The injection of foreign substances into the blood stream should always be considered a serious undertaking and the advantages and disadvantages should be carefully weighed before it is actually practised. The risks of intravenous injection frequently outweigh its probable benefits in (a) greatly debilitated patients, (b) the aged, (c) patients with hypertension and arteriosclerosis, (d) patients suspected of being subject to anaphylactic reactions, *e.g.*, asthma, urticaria, sensitiveness to drugs. Furthermore, the injection of substances likely to disturb or produce a subversion of the delicate physiological balance of the blood is contra-indicated. Substances markedly acid or alkaline in reaction, imperfectly purified substances, substances which do not dissolve in water, haemolytic agents, emulsions of fats and oils set up untoward effects which may be serious.

Technique of intravenous injection. The best veins to choose are those at the bend of the elbow, but if the patient is well covered these veins may be buried in fat and it may be easier to puncture one of the veins on the back of the hand. The latter are very moveable and it is often very difficult to puncture the vein, even when the needle is through the skin, as it recedes in front of the advancing needle and then suddenly slips away from it. There is a large vein at the back of the wrist running over the outer side of the head of the radius between the tendons of the extensor carpi radialis longus and of the extensor pollicis brevis which is extremely useful, especially in children, in whom it is often as big as the little finger. The vein is not usually blue but can very easily be felt, and if congestion is caused it will stand out very prominently. The disadvantages in using this vein are that the skin over it is usually tough and there is a nerve just under it which may be accidentally injured.

The skin over the vein should be sterilised with alcohol. If iodine is used it must be washed off with alcohol, otherwise it will increase the difficulty of seeing the vein. Washing the skin with xylol will increase the visibility of the veins but this is seldom necessary. Engorgement is caused by putting a rubber ligature round the arm above the point at which the vein is to be punctured. This ligature must be tight enough to stop the venous return but not tight enough to stop the arterial flow to the limb. Further congestion may be caused by gentle upward massage or by rapid extensor and flexor movements of the limb by the patient. The patient should be either lying down or sitting at a table with the elbow on a small pillow. The syringe should be held in the right hand at an angle of about fifteen degrees with the skin surface and entered upwards and along the long axis of the vein. The point may enter the vein immediately or the vein may slip to one side; in the latter case the point of the needle must be made to follow the vein, pressing into the side of the vein until it is pierced. Directly the vein is punctured, blood will enter into the barrel of the syringe, which has been previously loaded with the dose that is to be injected. The congesting band is now released and the solution slowly injected. The injections should in all cases be given as slowly as possible; not less than two full minutes should be taken over the injection of a maximum dose. When once the point of the needle is in the lumen of the vein, every effort must be made to prevent its either slipping out again or being pushed through the opposite wall of the vein. During the loosening of the constriction and the pressing home of the plunger the operating hand must be steadied by being rested on the arm of the patient. If at any time during the operation there is any doubt as to whether the point is within the lumen of the vein, the operator can satisfy himself by slightly withdrawing the plunger again. If the needle is still in position

blood will again flow into the syringe. Great care must be taken that no air escapes into the vein from the syringe.

The syringe that is used must be all glass or glass and metal. The smaller the syringe, the easier it will be to give the injection. A 5 c.cm. syringe will generally be found the most useful one for this purpose.

In children, who are very likely to wriggle during the operation, a good method is to hold the syringe in the right hand and with the left hand grip the arm so that the back of the elbow lies in the hollow of the hand and the first two fingers and the thumb can be approximated in front of the elbow; as the needle is passed into the vein the barrel of the syringe is gripped between the fingers and thumb of the left hand so that the syringe and the arm cannot possibly move independently. It will not be found necessary to grip so tightly that the venous flow is stopped.

The drugs used must be of established purity determined by chemical or biological methods and should be freely soluble in ordinary solvents. Substances which are imperfectly soluble should on no account be injected into the vein unless they are in a colloidal state.

The solution. (a) The water used for the solution of the agent to be injected must always be freshly distilled. Ordinary commercial distilled waters should be avoided, if possible, as they are liable to produce rigors and temperature. Besides, there is every chance of ordinary distilled water turning acid immediately after distillation, owing chiefly to the absorption of CO_2 from the atmosphere.

(b) Sterility of the solution just before injection is essential. This may be attained by autoclaving the solution if there is no chance of the drug breaking up by heat.

(c) The possibility of decomposition of the solution should be borne in mind. Heat converts a part of NaHCO_3 into a much more caustic and alkaline carbonate. Such substances as strophanthin are decomposed when their solutions are put up in soft glass ampoules, owing to the liberation of alkali from the glass. The physician should see if hard glass has been used for such ampoules before giving the injection.

(d) The reaction of the solution is important. All solutions for intravenous use should conform as closely as possible to the reaction of the normal blood which is slightly on the alkaline side of neutrality (pH 7.4).

(e) Solutions should always be as nearly isotonic with the blood as possible whenever the volume of fluid to be injected is large. Exception to this are conditions such as cholera and high intracranial pressure, when hypertonic solutions are necessary.

(f) The rate of injection of the solution should be slow in order that the circulation is not overwhelmed with large volumes of the fluid which it cannot cope with rapidly. Injection at a slow rate is specially

important in connection with potent drugs like arsenicals, and antimonials.

(g) The temperature of the solution should be approximately that of the body, otherwise unpleasant reactions might result.

Reactions and dangers. There are various risks attendant on intravenous therapy and in order to avoid them, those using the method should thoroughly familiarize themselves with the details of the technique. When it is realised how well the equilibrium in the blood is maintained, the grave consequences of its disturbance, the relative ease with which it may be upset and the serious accidents which may follow, will be obvious.

Dangers from the solution used. Anaphylactoid phenomena evidenced by rigors, chill, vomiting, sweating and pyrexia. Rigors and fever may follow immediately after intravenous injection, especially if large volumes of substances like saline or glucose are given. Such reactions are very disturbing and their real nature is not clear. Seibert (1925) showed that distilled water frequently contains a pyrogenous body which is the product of its contamination with living organisms. This pyrogen is produced by the growth of the organisms and is not present in freshly distilled water. The water used should therefore be freshly distilled, unless it is properly preserved. The other view is that the anaphylactic reactions are the result of physico-chemical disturbances in the plasma set up by rapid changes in the blood. The temperature of the fluid at the time of its entrance into the vein is also important. It should be realised that the temperature of the solution in the funnel or glass barrel used in the gravity method is not the same as that at the tip of the needle, for the solution cools down during its passage through the rubber tubing.

Danger from the agent employed. No agent should be used for intravenous injection which has got any deleterious effect on the circulation and is therefore likely to produce dangerous reactions. Rendle Short has described a dangerous condition from the intravenous use of sodium chloride in large quantities. If the total quantity injected is very large—10 gm. or more—a condition of 'hydræmic plethora' is likely to be induced by dilution and increase in the total volume of the blood.

It has also been shown that the specific gravity falls from 1064 to 1054 after an injection; the kidneys and lymph channels promptly excrete the excess of fluid and may overshoot the mark, so that eventually the specific gravity may rise to 1067; the total blood is less in bulk and even more concentrated than it was before. This does not occur if the supply of fluid is kept up by administering saline per rectum.

If the kidneys are not capable of excreting water and salt quickly enough, there will be water-logging and some degree of dropsy may occur. This may take the form of fatal cedema of the lungs. This danger has frequently been met with following saline transfusion, especially in patients with nephritis.

Thrombosis and embolism. These conditions have frequently been mentioned as the most dangerous outcome of intravenous therapy, and numerous instances of death following thrombosis and embolism of the pulmonary capillaries have been recorded. It is possible that sudden death might follow intravascular clotting and an embolus might stop the heart at any moment by blocking the coronary arteries. But serious results attributable to thrombosis or embolism are seldom met with in practice and one or two bubbles of air injected with the solution in the syringe do not produce 'air embolism.' Nevertheless there is a chance of thrombosis starting at the site of injection, if the agent injected is sufficiently irritant to cause damage to the endothelial lining of the vein. To prevent this, an additional quantity of saline should be injected to wash down the irritant drug. This is the usual practice with drugs like salvarsan.

Associated dangers. These are not directly due to the injection but are the results of faulty technique, occurring especially with those who are not experienced in the art of intravenous injection. The injection of drugs like arsenic, antimony, calcium and iodine, in the perivascular tissues is fraught with serious results in the shape of acute inflammation and abscess formation requiring surgical intervention. Fibrosis (local) leading to limitation of movement of the elbow joint is not an unusual complication. Tetanus is also known to have occurred as a result of injection with imperfectly sterilised

syringe and needle or improper attention to sterilisation of skin. All these dangers can be prevented with proper care and attention on the part of medical practitioners.

INTRAVENOUS THERAPY

A host of drugs are now being used in intravenous therapy and an enumeration of all these preparations is not necessary. The list of such drugs has been rapidly growing of late years with the introduction of new remedies, mostly the outcome of chemotherapeutic research. A systematic account of all these drugs is difficult, for all of them have not been studied with sufficient thoroughness. The important drugs in use can be classified as follows:—

1. Substances that bring about a change in the blood condition.

(a) Change in volume—saline, glucose, blood transfusion, etc.

(b) Change in reaction—sodium bicarbonate.

(c) Change in coagulability—calcium chloride.

2. Specific agents against protozoal organisms—cinchona alkaloids, emetine, compounds of antimony, arsenic and mercury.

3. Agents used against bacterial organisms—dyes, iodine, hexamine.

4. Immunity-producing agents,—sera, vaccines.

5. Anaesthetic agents—hedonal, magnesium sulphate, evipan-sodium.

6. Agents that cause sclerosis of the veins—phenol, etc.

7. Diagnostic agents—uroselectan B, sodium-tetra-iodo-phenolphthalein.

1. SUBSTANCES THAT BRING ABOUT A CHANGE IN THE BLOOD CONDITION

Intravenous saline infusion. Intravenous administration of saline solution is attended with such marvellous results that it is considered as one of the triumphs of intravenous therapy. Its application has come to the forefront in the treatment of wound shock during the recent

War. The successful application of saline in the treatment of cholera has made it the most popular remedy. Every medical man in the tropics should, therefore, be familiar with the technique of injection.

The chief indications for intravenous saline infusion are: (a) To increase blood volume, (b) to combat toxæmia and (c) to effect dehydration.

(a) Intravenous injection of saline is pre-eminently indicated in conditions of surgical shock. This condition is characterised by a fall in blood pressure and paralysis of the capillaries, so that all the blood in the circulation accumulates in the splanchnic area. The heart does not get sufficient blood to pump into the systemic circulation and the higher centres of the brain suffer. In this condition, a saline infusion by restoring the failing circulation, might prove of immense benefit to the patient. Sometimes, however, the results of a saline transfusion are disappointing, owing possibly to increased capillary permeability which permits fluids, salts and even plasma proteins to leak out of the blood vessels into the tissues. To combat this difficulty, Bayliss, during the Great War resorted to colloidal solutions containing gum acacia. Such solutions were apparently more effectively retained than simple chloride solutions and the procedure was considered life-saving in many instances. Bayliss claimed that by this means disastrous results can be prevented even when the blood corpuscles are reduced to half their original number, a reduction otherwise fatal. As acacia is a colloid and the blood vessels are impermeable to colloids, it attracts or retains water in the blood. Doubts have, however, been expressed regarding the safety and efficacy of this procedure. Hanzlik and his collaborators found intravenous injection of gum acacia solutions harmful and dangerous. These dangers could probably be avoided by greater care in the selection of the gum used and the preparation of the solutions. This form of therapy has not been used much during recent years.

Intravenous saline infusion is again the best form of treatment in cholera. Cholera is characterised by excessive vomiting and purging, and consequently there is tremendous loss of water from the system. The blood becomes thick and the specific gravity rises; in fact, dehydration may be so marked that the delicate cells of the body suffer serious injury from water starvation. If at this juncture, the fluid loss is compensated by liberal quantities of saline solution, the crisis can be avoided in most cases. A good deal of care is necessary to determine the amount of saline to be injected. An excessive quantity of saline introduced into the circulation at a rapid rate may give rise to oedema of the lungs and right heart failure in certain cases. A simple way suggested for avoiding these difficulties is to introduce the saline after determining the specific gravity of the blood. A litre of normal saline for every unit rise of specific gravity above 1060 is considered a safe quantity, provided no other complications are present.

The disadvantage of normal saline is that it passes out of the circulation very quickly and the improvement obtained is short-lived. As in cases of surgical shock, Bayliss' gum saline transfusion is not particularly advantageous, as the aim of treatment in cases of cholera is to antagonise the tissue thirst rather than to increase the blood volume through the agency of a non-diffusible colloid. Rogers successfully used hypertonic saline containing 120 grains of sodium chloride to one pint of water. This procedure obviates the necessity of frequent repetition of injection to keep up the blood volume, as a hypertonic solution does not pass out of the circulation as quickly as normal saline.

(b) Saline solutions are administered intravenously to combat various forms of toxæmia. The toxæmia resulting from high intestinal obstruction and stasis is associated with marked dehydration and concentration of the blood. Here, a litre of a 1.0 per cent. solution of sodium chloride is given intravenously two to three times a day, with striking improvement. Similar gratifying results after saline infusions are also obtained in cases of gastro-jejunostomy and cholecystectomy where toxæmic symptoms have supervened after operation. After excessive burns and gas poisoning the tissues suffer from marked dehydration, and in these conditions intravenous saline infusions have sometimes been of remarkable utility.

(c) Of late years, intravenous injections of hypertonic saline solutions have been largely used for reduction of increased intracranial tension. This is important in brain surgery and the procedure has made many operations on the cerebrum possible, which otherwise could not have been attempted for fear of causing post operative hernia of the meninges. It has been pointed out that it is possible to diminish the intracranial pressure by the injection of a 35 per cent. solution of sodium chloride into the blood stream and that this is accompanied by a reduction in the cerebro-spinal fluid pressure. Malone has successfully used a strong salt solution to control excessive intra-cranial tension and for the relief of 'tension headaches,' such as may occur in persons suffering from cerebral tumours. The effects appear to be due to the osmotic pressure of hypertonic solutions which causes withdrawal of fluid from the tissues generally, and probably also decreases the formation of cerebro-spinal fluid.

Intravenous Glucose

The intravenous administration of glucose solution has now attained a position of considerable importance as a rational therapeutic measure in general medicine, obstetrics and surgery. It is difficult to enumerate the various pathological states for which glucose has been utilised with benefit. As a nutrient

in undernutrition, it has been widely employed. It was originally employed for its diuretic action. Many people use it for the combined purposes of nutrition and prevention of acidosis in patients suffering from vomiting or shock or in gastro-intestinal disorders.

Dosage. The average dose for an adult is about one gm. per kilogram of body weight. An average adult weighs between 50 and 75 kg. so that 75 gm. can be given as the initial dose, subsequent doses being 50 gm.

Solvent. The glucose given by this route should be chemically pure and should be dissolved in freshly double-distilled, uncontaminated water and not in salt solution or sodium bicarbonate solution, as has been sometimes recommended. In the preparation of a single dose, 50 gm. of the glucose is carefully weighed and then dissolved in 200 c.cm. of freshly distilled water, using only glassware which has been thoroughly washed in distilled water. Before sterilisation the solution should be filtered at least five or six times to remove tiny particles of dust or cotton fibres. For the sake of simplicity in making any necessary calculations for dilutions it is convenient to have each flask contain 25 gm. of glucose in 100 c.cm. of water (25 per cent.) or a half dose.

Fresh double-distilled water is used for preparing glucose solution for intravenous injections and as a diluent of the more concentrated solutions in ampoules now on the market.

Concentration of solution. A 25 per cent. solution (50 gm. in 200 c. cm. of water) is the generally desirable strength. A 6 per cent. solution was at first used, but the concentration has been gradually increased up to this point, as the direct result of the observation that the stronger the solution the more rapid and lasting are the effects. Moreover, some extremely unpleasant consequences have followed in some instances, notably in pneumonia, when the vascular system has been rapidly overloaded by a large volume of weak glucose solution. It is apparent that if the solution is weak a large amount must be given in order to carry a therapeutic dose of the glucose. It is, we believe, a distinct advantage to use a strongly hypertonic solution because its hypertonicity actually favours a more rapid inter-change between the tissues and the blood stream, so that toxins are diluted, oedema lessened, and the sugar seized and stored more rapidly by the tissues.

If more fluid is required by the body, it is safer to consider this as an entirely separate matter and administer it as sub-mammary infusions of salt or weak glucose solution.

A ten per cent. solution of glucose should be considered as about the lowest limit of safety in dilution and a 25 per cent. solution should be preferred unless there is some definite indication for immediate and rapid administration of additional fluid by the blood stream route. It is quite likely that certain reactions are attributable to injection of an excess of distilled water when weaker solutions are used.

Sterilisation. The flasks of glucose solution after being properly stoppered with cotton plugs in gauze and the top sealed with lead foil, should be sterilised in a steam steriliser for one-half hour at 100°C. on three successive days. It may be prepared more quickly for emergencies by being sterilised in an autoclave at 15 pounds pressure for twenty minutes. In either case sufficient space should be left between the level of the solution in the flask and the stopper so that the solution will not be forced by vacuum up against the stopper. This is also a precautionary measure against the possibility of splashing the solution against the stopper in any handling of the flasks.

Solutions showing caramelization or sediment after sterilisation should be discarded.

Age of solution. Glucose solutions kept in flasks stoppered with cotton, or cotton and gauze, and sealed with lead foil will show comparatively little change in hydrogen-ion-concentration over a considerable period of time, even though buffer salts have not been added, so that solutions may be prepared in advance of the need for them. Flasks of glucose solution kept on a laboratory shelf for six months showed practically no change in acidity. As a matter of fact, the greatest variation takes place during the course of the sterilisation of the solution and from then onwards it remains fairly constant.

Solutions should preferably not be kept longer than four weeks unless hermetically sealed, and the fresher the solution

the safer it probably is. Reactions can rarely be traced to those solutions that are not older than two to four weeks.

Ampoules of glucose solution:—Ampoules of glucose (dextrose) solution are now on the market and have been carefully and properly prepared by manufacturers. Those containing preservatives should be avoided.

Hospitals which are using large amounts of glucose intravenously find it economical to prepare their own solutions, but for small services or emergency work these ampoules are very useful. For convenience and compactness they are usually prepared as 50 per cent. solutions (25 gm. of glucose in 50 c.cm. of water) with directions for diluting. If freshly distilled sterilised water cannot be obtained for this purpose, it is probably safer to inject the solution as it comes from the ampoule even though so highly concentrated.

Technique of administration:—An individual can utilise only 0.8 gm. per kilo. of body weight per hour of injected glucose and to give more than this amount by too rapid a rate of injection results in its immediate excretion through the urine. Calculating from the rate of utilisation, the injection should be given slowly at the rate of 4 c.cm. per minute for a 25 per cent. solution, and during this period the solution should be kept warm. The solution is ordinarily injected from a salvarsan tube, using a small calibre needle, and having the tube coiled in a basin of hot water to keep the temperature of the flowing fluid from 100° to 110°F.

Fresh rubber tubing should not be used until after it has been thoroughly washed in running water, then boiled in clean water (without sodium carbonate), again washed, and finally sterilised in an autoclave. Chemical contamination from new rubber tubing has been suggested as a cause of reaction following these injections.

The salvarsan tube and the connecting tubes, as well as the rubber tubing, should be thoroughly cleansed and then sterilised in an autoclave because when merely boiled, sediment from water is often to be seen within the glass. Before beginning the injection the system should be rinsed out by running distilled water through the salvarsan tube, the rubber tubing, the connections and the needle.

Blood Transfusion

The method of infusing new blood, from one man or animal into another man, came into being as early as 1650. Since then, it has been practised from time to time but on account of the occurrence of frequent catastrophies it was entirely given up. The method almost received its death-blow at the hands of William Hunter who wrote "For practical purposes all the advantages to be gained from transfusion may be equally well and more readily obtained by infusion of a neutral saline solution of common salt." This utterance, coupled

with the difficulty of technique in performing the operation successfully, kept the method practically out of the therapeutic field until recently (1910) when Moss described the four human blood groups. Since then transfusion has again gained popularity and since the Great War, it has come to be universally recognised as a very useful therapeutic measure.

Indications. These may be classified under four main groups. (1) Acute hæmorrhage and anæmia. (2) Chronic anæmia, to tide the patient over an operation, or to benefit the condition, prolong life and in the hope of cure, *e.g.*, Addisonian anæmia, anæmia of pregnancy, (3) In hæmorrhagic diseases. (4) In general toxæmia of bacterial or chemical origin.

Acute anæmia due to hæmorrhage is most successfully treated by blood transfusion. During the Great War it was amply proved to be a live-saving measure in conditions of traumatic hæmorrhage and shock. Its value in post-partum hæmorrhage and ruptured ectopic gestation has also been widely acknowledged. Blood transfusion is now thought to be superior to transfusion of saline and gum solution. After saline, the patient often improves for some time and then goes down again; after blood transfusion, on the other hand, the immediate benefit may not be striking but the permanent results are ensured. The reason of this is that transfused cells actually carry oxygen to the starved tissue cells, which gum saline cannot do.

In gastro-intestinal hæmorrhage, blood transfusion is distinctly useful and some authorities recommend small repeated transfusions rather than one large one. The fear that by increasing the arterial pressure, transfusion may induce bleeding from the original site of the ulcer seems to be unfounded, for the rise in arterial pressure is never more than 20 mm. of mercury and it is too transient to produce any appreciable effect.

In chronic anæmias due to repeated small hæmorrhages, debility, gynæcological conditions small repeated transfusions of blood have been employed in order to render feasible a surgical operations. Doubts have been expressed as to what extent blood transfusion does good in chronic anæmias. Theoretically, the problem is not so simple as in the case of acute hæmorrhage, for the etiological factors persist and must be taken into account. In Addisonian anæmia, though transfusion has been practised a lot with the idea of supplying healthy blood with its hormones and antibodies so as to stimulate the activity of the bone-marrow, the efficacy of this procedure is doubtful. It is difficult to imagine how anything could stimulate the blood-producing organs which are at fault and if they are stimulated it is probable that abnormal cells, instead of normal red blood cells, may be produced.

In hæmorrhagic diseases. In these diseases, transfusion is beneficial as it supplies the necessary thrombogenic factors, fibrinogen and blood

platelets. If the citrate method of transfusion is used, there is no difficulty in spite of its anticoagulant action.

(i) **Purpura hæmorrhagica** is characterised by bleeding from mucous surfaces, a diminution in the number of blood platelets in the shed blood and a prolonged bleeding time. Repeated blood transfusion was formerly the chief form of treatment but splenectomy is now resorted to.

(ii) **Melæna neonatorum**. Blood transfusion is the only rational and successful treatment. There are technical difficulties in performing blood transfusion in the new-born but if done successfully, one transfusion is sufficient in the majority of cases. Failing this, whole blood may be given intramuscularly.

(iii) **Hæmophilia**. Although the blood platelets are never diminished in this disease, blood transfusion is beneficial both to counteract anæmia and to prevent bleeding during an operation. The hæmostatic effect is supposed to be due to the introduction of fresh blood platelets.

(iv) **Jaundice**. Transfusion has been tried in some cases of severe jaundice with prolonged coagulation time, as a prophylactic measure before surgical operations. The results however are not uniformly successful.

(v) **In black-water fever**. Transfusion of whole blood at the time of or immediately after an attack of fever is a useful therapeutic measure. The fear of causing more hæmolysis should never be allowed to prevent blood transfusion in desperate cases.

General toxæmia—bacterial or chemical. In chronic infections and intoxications, the value of transfusion has been acknowledged. Chronic debilitating conditions associated with malnutrition and marked anæmia have been treated frequently by blood transfusion with gratifying results. These conditions are mostly the outcome of chronic septic absorption from some unknown focus. In sprue, which may be considered to be a disease produced from bacterial intoxication, blood transfusion has often proved beneficial.

In acute toxæmic conditions, the general opinion is against blood transfusion inasmuch as the benefit derived is doubtful and actual harm may follow from the formation of abnormal agglutinins and hæmolysins. It has, however, been thought by some that transfusion may increase the patient's general resistance, possibly because the infused blood may happen to contain specific antibodies. With this idea in view, Wright and his co-workers have advocated the method of *immuno-transfusion* the aim of which is to inject a blood which contains a bactericidal plasma and leucocytes, for both these elements play a rôle in defence. In conditions of acute septicæmia, the leucocytes seem to be paralysed so that the injection of vaccine, which is sufficient to stimulate antibody formation under all other conditions, is of no

avail. Immuno-transfusion under these conditions is said to act like a charm. The immunisation of the donor's blood is accomplished by giving him injections of vaccine, the blood in this way developing exalted bactericidal power. As the aim is to obtain large amounts of non-specific antibodies, the use of staphylococci is permissible and convenient, whatever may be the infecting agent of the patient. The increased hæmo-bactericidal power of the donor's blood is lost after about 48 hours, so the process has to be repeated in order to have a lasting effect.

In poisoning by chemicals such as CO, P, etc., the introduction of functionally active normal cells to carry oxygen, while the recipient's hæmoglobin is fixed by CO, has long been advocated and supported by experimental observations. If it is done after a preliminary venesection it gives good results.

Technique. Quite a number of methods of transfusion are in use. They fall into four main groups.

1. Direct transfusion (arm to arm transfusion).
- 2. Transfusion of unmodified and defibrinated blood.
3. Transfusion of citrated blood.
4. Transfusion of preserved red blood corpuscles.

(1) **Direct transfusion.** In this method, the radial artery of the donor and the basilic vein of the recipient are connected together by means of a thin rubber tube with a silver canula at each end, all the connections being sterilised and filmed by boiling in paraffin. The drawbacks of this technique are:—

(a) It is not possible to know how much blood flows from one to the other. (b) It is difficult to estimate the length of time that should be allowed to let the blood flow. (c) Sometimes, on account of active venospasm of the recipient, the blood from the donor does not flow properly.

(2) **Transfusion of unmodified blood (who's blood).** There are three different methods—Kimpton's, Unger's and Lindemann's. These methods came into being with the idea of obviating the difficulty of ascertaining the amount of blood that is being transfused in the 'arm to arm' method. The main principle on which these methods are based, is that the blood is drawn from the donor into a glass syringe with a stop-cock arrangement, and is then infused into the recipient as quickly as possible.

There is greater risk of massive clotting, for some time must necessarily be spent on the operation and consequently there is greater chance of intravascular thrombosis. Defibrinated blood has been used to get over the difficulty of thrombosis, but the complete defibrination of a specimen of blood is practically unattainable.

(3) **Citrated blood method.** Blood from the donor is drawn into a vessel containing sodium citrate solution (3.8 per cent. sodium citrate

solution is isotonic). As the blood is flowing into the vessel, it is kept constantly agitated to prevent clotting. This citrated blood is then injected into the recipient as quickly as possible though delay up to half an hour is not harmful.

A note of warning has been sounded by some authorities as to the toxicity of the sodium citrate injected. It is said that it gives rise to undesirable reactions and that it reduces the coagulation time of blood which is a distinct disadvantage when transfusion is done as a prophylactic measure before operative measures. Short (1919), however, found no difference in coagulation time after the injection of citrated blood in ordinary dosage (30 oz. of blood in 160 c.cm. of 3.8 per cent. sodium citrate solution).

(4) **Transfusion of preserved red blood cells.** Recent researches have shown that loss of blood after severe hæmorrhage can be replaced just as easily and efficiently by red blood corpuscles suspended in Locke's fluid as by fresh whole blood. The plasma cannot be preserved in citrate dextrose solution without the production of changes which might be toxic to the patient. Rous and Turner have demonstrated that red blood corpuscles preserved in citrated dextrose solution may be stored for several weeks and they still function when injected into an animal of the same species after a hæmorrhage. If however they are kept too long (4 weeks in man), they do no harm, but are rapidly removed from the circulation and the red blood corpuscles and hæmoglobin come down to the original level produced by the hæmorrhage. This method proved to be very useful during the War but it has not been practised in civil surgery.

Transfusion of blood from animal into man. This method has a great supporter in Cruchet. He strongly advocates its use and has adduced a lot of experimental evidence in favour of the method. According to him transfusion of heterologous citrated blood (animal to man) is almost as harmless as transfusion of homologous citrated blood from man to man, if the whole procedure is carried slowly. He maintains that the reactions noted after blood transfusion are due more to rapidity of injection than to hæmolysis or agglutination of the different elements of the blood. These claims have not been universally accepted and this method of heterologous transfusion has not attained any popularity.

Complications of blood transfusion. In many cases transfusion is followed by a minor reaction; soon after the transfusion has been given, the patient shivers and the temperature rises to 100°F. or higher. These small rises of temperature following transfusion are of common occurrence and may be due to one factor or to a combination of factors. The most frequent causes of this reaction are probably minor degrees of incompatibility of red cells and serum. This factor will be dealt with

at length below. Other causes are, a possible incompatibility of the white blood-cells; too rapid, too large, or too cold an injection; changes in the blood of the donor as a result of the presence in it of products of digestion, or as a result of the blood having been kept outside the body for a long time; changes induced by contact with foreign substances or to undue agitation of the blood previous to its administration. The most common complications are:—

To the donor. The risk is insignificant. A donor can without any harm to himself give a pint of blood and can walk about with ease after the operation. In practice it is always better to enjoin rest in bed for a day after removal of the blood. There may be a feeling of exhaustion and emptiness if more blood is withdrawn at one sitting. In America, there are lots of professional donors who allow themselves to be bled every 3 or 4 weeks. It has been proved by eminent workers in America that the same donor may be used repeatedly without ill effects to himself, provided sufficient time is allowed for the regeneration of the blood.

To the recipient. (i) *Hæmolysis.* If the blood of the donor does not match with the blood of the recipient. Alarming symptoms frequently appear when the samples of blood are not compatible, due either to the hæmolysis of the transfused corpuscles or to their agglutination. There may be vomiting, dyspnoea, urticarial rash, quick weak pulse and perhaps convulsions and coma at the time of transfusion. Hæmoglobinuria may appear after transfusion and deaths have been reported. The appearance of these reactions naturally gave such a rude shock to blood transfusion therapy at the time of its inception that it was practically abandoned for a long time. The researches of Moss regarding the different blood groups have brought the method again into general acceptance.

(ii) *Transmission of diseases.* Another risk is the communication of diseases, syphilis has been proved to be conveyed to the recipient, and malaria might also be conveyed.

(iii) Faulty technique may give rise to infection; but blood being definitely bactericidal, the occurrence of this complication is very rare.

(iv) *Anaphylaxis.* A phenomenon similar to anaphylaxis may sometimes occur in patients who have undergone repeated transfusion. This can be controlled by selecting a donor of a group identical with that of the recipient or by using different donors each time. If however the hypersensitive state becomes apparent, the transfusion should be immediately discontinued.

Blood groups. It is rather a strange phenomenon that the blood of different individuals, even of the same family, are not always compatible with each other. Shortly after birth the blood takes up the characters of one of the four groups and these apparently persist unchanged throughout life. The blood of a patient of a particular

group can be given safely to another person of that group but not necessarily to a person belonging to another group.

According to Moss, there are 4 classes of bloods, designated as groups I, II, III, and IV. The relative proportion of these groups (in America) and their suitability as donors, are given in the following table:—

Donor	Percentage frequency	Suitable if patient belongs to
Group I.	5	group I.
Group II.	40	group I. II.
Group III.	10	group I. III.
Group IV.	45	group I. II. III. IV.

The easiest method of determining the blood group of a donor is that of Vincent in which it is necessary to keep in stock sera of persons of group II and group III. This is tested on a glass slide against the blood corpuscles of the donor. A slight agglutination may be easily demonstrated within 5 minutes by the naked eye. If the sera of group II and group III are not available, direct matching tests may be done as follows:—The recipient's blood is drawn and is separated into serum and cells. The donor's blood is then drawn and is separated into serum and cells. The recipient's cells are then tested for agglutination against the donor's serum and the donor's cells are tested against the recipient's serum. If both reactions are negative for agglutination then the persons are of the same group.

According to Lloyd (1926) blood grouping tests are of definite value in the technique of blood transfusion and should always be done where possible. Direct matching tests have got their utility too. Extensive researches during recent years have made it clear that there might be abnormal types (other than the 4 blood groups) and high iso-agglutinin titre in certain donors belonging to group IV (universal donors). So from the point of view of the absolute safety of the patient in the operation of transfusion, direct matching tests must necessarily be done, over and above the routine group testing.

Intravenous sodium bicarbonate. The rationale of using alkalis in cases of acidosis has been much discussed. The hydrogen-ion-concentration of the blood under physiological conditions is always kept constant. It is only under pathological conditions that the alkali reserve of the blood undergoes some change, for various errors in metabolism and deficiency of oxygen result in the production of an excess of fixed acid and this is neutralised at the expense of alkali reserve. This exhaustion of the alkali reserve may be replenished by the administration of alkalis, preferably in the form of bicarbonates which are less toxic. For intravenous medication sodium bicarbonate may be used in a 5 per cent. solution. The usual prophylactic dose being 3 to 5 gm. It must be noted here

that the heat of sterilisation drives off some of the CO_2 and thus converts part of the bicarbonate into carbonate. This being highly corrosive to the subcutaneous tissue, great care should be taken to prevent any escape of the solution into the subcutaneous tissue when giving the injection.

Intravenous calcium. Calcium has been used very commonly by the intravenous route. A brief description of its uses and indications will therefore be useful.

The role of calcium in the body is not very clearly understood. It may be regarded, in one sense, as a very inert substance inasmuch as it is deposited in large amounts in normal tissues with a sluggish metabolism, such as bones, quiescent tuberculous foci, areas of fat necrosis and walls of degenerated arteries. The withdrawal of calcium from the body, on the other hand, ushers in symptoms of tetany. It is evident then that calcium is essential to the system. Howell has shown that the addition of calcium to perfusion fluid induces the isolated mammalian heart to beat more energetically and its complete removal puts a stop to the cardiac systole. Another important property of calcium is its influence on the clotting of the blood.

Uses. The property of calcium to stimulate the heart has been made use of in therapeutics in the treatment of various cardiac conditions. It has been used intravenously in pneumonia and in diphtheria to stimulate the heart enfeebled by the toxins of these infections. Its utility in these conditions is however doubtful. Great caution is required as in certain cases it has been known to give rise to thrombosis and other complications.

Calcium activates the fibrin ferment to induce clotting, and for this property it has been used universally to stop hæmorrhage. Administration of calcium by the intravenous route is considered to be the best, as absorption by the oral route is slow and uncertain especially when the hæmorrhage is severe and from inaccessible sources (e.g. gastric and duodenal hæmorrhage). Calcium is also used as a prophylactic measure before operative interference in weak and anæmic individuals in whom there is chance of free bleeding at the time of operation.

Tetany is pre-eminently a calcium deficiency disease and in grave cases of this disease when the patient is troubled with incessant convulsions, intravenous injections of calcium are of great help and may actually save the life of patients.

Injections of calcium are beneficial in tuberculosis of the lungs and particularly in tuberculous hæmoptysis. Administration of calcium combats some of the other manifestations of tuberculosis. The night sweats, the incessant coughing and the diarrhoea of intestinal tuberculosis are definitely checked. The mode of action is not clear, as calcium does not appear to have any marked deleterious effects on the tubercle bacillus.

Dosage. Calcium chloride, being an easily soluble salt, is most commonly given by the intravenous route. Recently, calcium gluconate has also been given intravenously. Collosal calcium is also given in this way but it is better to avoid it as it is likely to produce embolism.

It is always advisable to use the hypertonic solutions, as these are endowed with a greater degree of hæmostatic action than isotonic solutions. A 10 per cent. solution is very useful and of this 5 c.cm. may be given without untoward effects. Ten c.cm. of a 10 per cent. solution have also been frequently injected but may lead to ventricular fibrillation.

Dangers and reactions. When calcium is injected into a vein, great care must be taken to inject it as slowly as possible. Rapid injection and concentrated solutions produce a sensation of intolerable heat inside the body and the patient is apt to become restless during the operation. Ordinarily this sensation passes off in a minute or so, large doses are known to produce depression, ventricular fibrillation and immediate collapse. The depression of blood pressure which is an accompanying factor might also account for the collapse. Calcium chloride is an irritant fluid and if the solution escapes outside the vein, severe pain and necrosis of the surrounding tissues is likely to be produced.

Intravenous hydrochloric acid. Intravenous injections of 1: 1000 to 1: 1500 hydrochloric acid have been tried in the treatment of disease. Appreciable leucocytosis is undoubtedly produced by such injections but clinical benefit from such treatment is completely lacking.

2. SPECIFIC AGENTS AGAINST PROTOZOAL ORGANISMS

Intravenous medication of specific remedies against protozoal infections is dealt with in Part III.

3. AGENTS USED AGAINST BACTERIAL ORGANISMS

Intravenous iodine. Intravenous administration of iodine has now a definite place in therapy. The evolution of the idea of injecting iodine into a vein is purely empirical, its external antiseptic action suggesting its use internally. No rational explanation of the nature of the action of iodine given intravenously is available. The idea that the action of iodine in the blood stream is almost identical with its external action cannot hold ground in view of the fact that ordinary therapeutic doses are never capable of attaining a lethal concentration for bacteria in the blood stream. One grain of iodine (contained in about 2 c.cm. of tincture of iodine B. P., the usual therapeutic dose) in 5 litres of the blood cannot have any direct antiseptic action. There must therefore be other factors responsible for the effects which are produced. The view that iodine stimulates the thyroid gland and thereby produces its beneficial results is now generally accepted. Assuming that the thyroid

gland plays a part and the action is an indirect one, small doses of iodine ought to act as well as large doses. It has been shown from case records, however, that larger doses (*i.e.*, 2 c.cm. of tincture of iodine) give decidedly better results than smaller ones. The present position of our knowledge regarding the rationale of the intravenous injection of iodine is thus not quite clear. There is however always a marked leucocytosis after intravenous injections of iodine. This might explain the beneficial results, for increase in leucocytes means an increase in the resistance and fighting powers of the body.

Uses. Injections of iodine have been used in the following conditions :

Septicæmia. Tincture of iodine in distilled water or aqueous solution of iodine has been used in plague septicæmia with gratifying results. It has been given an extensive trial by various workers and the consensus of opinion is that intravenous injections of iodine are perhaps the best remedy against plague. After one to two injections, the general condition of the patient improves, the delirium disappears and the temperature shows a marked tendency to return to normal. In influenzal septicæmia, erysipelas and typhoid fever, it has also been used with good results. As a matter of fact, iodine intravenously has been and is still being used empirically in almost all cases of remittent pyrexia of unknown origin characterised by delirium and rigors, and most cases are said to respond favourably.

Pyæmia. In pyæmic conditions following septic tonsils and sinus trouble, chronic hip diseases, abortion and other puerperal conditions, iodine intravenously is one of the most potent remedies we have at our disposal. Bell (1924) recommended iodine instead of vaccine in places where bacteriological facilities are not available, and he even asserts that iodine will probably replace vaccine therapy in pyæmia.

In lobar pneumonia, post-operative pneumonia and similar lung conditions iodine is of great value. It not only clears up the local condition in the lungs, but also improves the general toxæmia which is so frequently associated with these conditions. The leucocytosis which is set up might account for the beneficial effects which are produced.

Joint troubles like synovitis and arthritis. Iodine has been used in synovitis of the joints with beneficial results.

Chronic ulcers including corneal ulcers. These conditions sometimes respond very well to iodine treatment.

Malaria and kala-azar. Injections of iodine have been tried in both these diseases by Bracho (1923) with indefinite results. Other workers have definitely found them to be useless.

Syphilis. Iodine intravenously has been found to be of no value in syphilis, although potassium iodide is very efficacious in certain stages.

Goitre. Reddi (1927) has recorded a few cases of improvement in goitre by the use of sodium iodide in the China hills.

Dosage. Tincture of iodine diluted in distilled water and aqueous solution of iodine are both used for intravenous medication. The B. P. tincture is more convenient, as it is always available and does not require special preparation. Most people, however, use the aqueous solution with the idea that there is less chance of thrombosis at the site of the injection. Both the preparations, however, are equally effective. One c.cm. of tincture iodine diluted with 2 to 5 c.cm. of distilled water is the dose ordinarily given, the maximum dose being 2.0 c.cm. diluted with 10 c.cm. of distilled water.

The aqueous solution of iodine contains iodine crystals 24 grains, potassium iodide 36 grains, dissolved in one ounce of distilled water. One to 2 c.cm. of this can safely be given (1 c.cm. equals approximately 1 grain of iodine). This solution might be further diluted according to the condition of the patient and the discretion of the physician.

Dangers and reactions. There are no serious risks attendant on these injections. Frequently after an injection febrile reactions associated with rigors set in. These do not require any special treatment excepting rest, hot drinks and warm blankets. Urticaria and iodism have been recorded from time to time but these occur very rarely. Thrombosis of the vein at the site of injection is due to faulty technique and with care can be avoided.

Hexamine (urotropin). Hexamine or hexamethylenetetramine is a compound prepared by the interaction of ammonia and formaldehyde. Hexamine derives its usefulness in therapeutics from its property of easily liberating the latter substance from its combination. This liberation is brought about either by the action of heat or by weak acids. Hexamine is usually given *per os* and is a valuable urinary antiseptic as formaldehyde is easily liberated in the urinary passages. There is also a chance of the formaldehyde being liberated in the stomach by its interaction with the acid of the gastric juice. It is therefore suggested that it should be given by the intravenous route; the blood being alkaline, hexamine will not be broken up in it.

Uses. In septic conditions of the genito-urinary tract, *e.g.*, cystitis and pyelitis, hexamine intravenously is now used universally with very satisfactory results. *B. coli* infections clear up very rapidly. Gonococcal cystitis also responds favourably in most cases. The usual dosage employed is 5 to 10 c.cm. of a 10 per cent. solution. In acute cases, pain, fever and dysuria disappear after one or two injections. In chronic cases more injections are required, the treatment being combined with saline diuretics and local bladder washes.

***B. coli* septicæmia.** Hexamine has been used with satisfactory results in these conditions. *B. coli* septicæmia is the usual outcome of primary infection of the genito-urinary tract and is especially common during the puerperium. It sometimes appears in a very

virulent form and is not amenable to any form of treatment excepting hexamine intravenously. Stronger solutions of hexamine (20 per cent.) have been tried in these conditions on alternate days, without any untoward effects.

Influenza. Intravenous injections of hexamine were extensively used during the influenza epidemic of 1918. One or two injections were enough to control the temperature and the general condition of the patient improved; the naso-pharyngeal catarrh and muscular pain disappeared very quickly. Complications like broncho-pneumonia were unknown in cases treated with hexamine.

Encephalitis lethargica and meningitis. Hexamine has been tried in encephalitis lethargica, especially during the acute stage in doses of 5 c.cm. of a 20 per cent. solution daily for 10 days, with beneficial results. In cerebrospinal meningitis too it has been used extensively.

Mastoiditis and sinusitis. Hexamine has been tried in the treatment of all inflammatory conditions of the mastoid and the sinuses. Such cases usually react well in the early stages but when there is actual formation of pus, surgical intervention is the only rational treatment.

Scabies complicated with suppurative lesions all over the body has been treated with hexamine injections. Although the drug does not act on the causative organisms, it helps to clear up the suppurative condition. The routine suggested is to give 10 per cent. solution in normal saline in doses of 10 c.cm. daily for 3 to 4 consecutive days. The external lesions are washed with plain hot water and a mild sulphur ointment applied.

Acute and chronic nephritis. The rationale of its use in these conditions cannot be explained but diuresis appears to be fairly constantly produced; the irritating effect of formaldehyde probably stimulates the renal epithelium. It is better to withhold hexamine, for it might actually cause further damage to the renal epithelium.

Dangers and reactions. Hexamine injections are attended with no risk if the following points are attended to: (1) the water used must be double-distilled and sterile, (2) the solution should be made in cold water, (3) no acid should be in contact with the solution.

Cases of hæmorrhagic cystitis following intravenous injections of hexamine in doses of 5 to 10 c.cm. of a 40 per cent. solution have been recorded. This might be ascribed to liberation of large quantities of formaldehyde in the bladder irritating the already congested and inflamed mucosa. Weaker solutions, however, seldom cause any trouble.

Colloid metals. Certain metals and metalloids in the form of colloidal solution are used in therapeutics. The metal exists in these solutions in a state of very fine subdivision, and the colloidal solution of a metal resembles more nearly a suspension of metallic dust, than it does a solution. The particles in this condition are one to one hundred micromillimetres in diameter and therefore readily pass through the capillaries.

and do not produce emboli. They consist of aggregates of a large number of molecules and very few ions of the metal are present. The whole of the metal, in a colloidal solution is therefore in an inert state and the free ions which are liberated are so few that they do not produce irritation, but are sufficient to produce an oligodynamic action which inhibits the growth of bacteria. Moreover, the metal in this state may pass quite readily into ionic conditions, *e.g.*, by the action of tissue fluids, bacteria, etc., and may then exert the ordinary action of metal. Bayliss has criticised the claims that have been put forward in favour of the pharmacological activity of the colloid metals. He points out that the 'electrical charges' and the 'surfaces' in dilute solutions of colloid metals are insignificant in comparison with those that already exist in the protein systems of the blood and tissues; and that many of the effects attributed to the metals are due to the protective colloid and others to the acidity of the solutions.

Most of the electrically or chemically prepared colloids are unstable. For clinical use, they are 'stabilized' by addition of organic colloids, *e.g.*, gelatin, albumen, etc.

Colloidal metals are commonly used for the treatment of infective conditions, *e.g.*, puerperal septicæmia, pneumonia, pleurisy, peritonitis, influenza, typhoid, tuberculosis, and other febrile conditions. Repeated intravenous injections may often produce marked irritation of the lymphoblastic tissue of the spleen, lymph glands and bone marrow. Moreover, colloid solutions, deteriorate on keeping and gradually pass into the ionised form, which may produce the ordinary systemic effects of the metal. They may also rapidly pass into insoluble forms and may then produce embolism. These effects should always be taken into consideration while using a colloid metal.

The following are the preparations commonly used.

Colloidal copper solution. It is generally used in cases of inoperable malignant growths, and it is believed that on the surface of the metallic particles, it supplies oxygen necessary to prevent abnormal cell growths. Strength of the solution used is 1: 2000 and the dose 1/2 to 1 c.cm. intravenously. The solution is to be made isotonic at the time of use (sodium chloride should not be used for the purpose, since electrolysis may cause precipitation).

Collosol iodine. It is used as a substitute for iodides in cases of syphilis, rheumatic affections, tuberculosis, bronchial and nasal catarrh. Ten to 200 c.cm. may be used intravenously, and in cases of pyæmia and to produce softening of fibrous tissue as much as 300 c.cm. has been given intravenously.

Colloidal mercury solution. This is used in syphilitic affections in doses of 5 c.cm. of 1 in 2000 solution (0.0025 gm. of metals). The solution may be isotonised at the time of injection by 1 c.cm. of 5.5 per cent. sodium chloride solution.

Colloid silver solution. It has been particularly used as an internal antiseptic in puerperal septicaemia and other infections. Phagocytosis is perhaps somewhat increased for some bacteria but not all. The dose is 5 c.cm. of 1: 2000 solution intravenously.

Colloidal gold solution. Orargol is a preparation of colloid gold (0.01 per cent.) and silver (0.09 per cent.). It is used in doses of 5 c.cm. intravenously or intramuscularly to abort attacks of pneumonia, influenza or erysipelas.

Colloid bismuth has been largely used in the treatment of syphilis and is described in a separate chapter.

Collosol sulphur. It is used in skin affections and wherever sulphur is indicated through excessive elimination, solution of 1: 1000 in doses of 1 to 2 c.cm. is used, which at the time of injection is made isotonic with 0.4 c.cm. of 5.5 per cent. saline.

4. Intravenous administration of immunity-producing agents, *e.g.*, sera and vaccines, is dealt with in Part V.

5. INTRAVENOUS ANAESTHETICS

Magnesium sulphate. A soluble salt of magnesium injected intravenously into a rabbit produces a complete loss of excitability in all parts of the nervous system. Not only is the central nervous system paralysed, but the drug also produces a curariform action and paralysis of the motor nerve endings. In concentrations of 0.1 per cent., magnesium in the blood stream will produce this action and the action is immediately abolished by injecting an equal amount of calcium. The pharmacological action of magnesium differs fundamentally from other hypnotics. Most hypnotics act first upon the higher centres of the brain and produce a descending paralysis of the central nervous system but magnesium acts indifferently upon all the parts of the central nervous system. The action of magnesium is a reversible one and if an animal is kept alive by artificial respiration it recovers after a time from magnesium anaesthesia.

Therapeutic uses. 1. Intravenous injections of magnesium sulphate have been recommended as a treatment preliminary to ether anaesthesia, the drug acting very much like morphia before chloroform, in reducing the minimal concentration necessary to induce anaesthesia. Cases of excessive oral administration of magnesium sulphate are known to have caused a comatose condition in man, but the usual purgative doses do not produce this effect as magnesium is very slowly absorbed from the gut and is rapidly excreted by the kidneys.

2. To relieve labour pains, intravenous injections of magnesium sulphate have been tried, instead of morphia, in morphia-scopolamine or twilight sleep. Here magnesium acts as a synergist to scopolamine and potentiates the action of the latter drug. It is, however, seldom used for this purpose.

3. Tetanus. In this condition intravenous injections of magnesium sulphate have been employed 10-15 c.cm. of a 3 per cent. solution being injected without any danger to the patient. Stronger solutions produce sudden coma and death from respiratory paralysis. A 20 per cent. solution of magnesium sulphate may also be used, alternating with carbolic acid, to control the tetanic convulsions.

4. Eclampsia. Reports on the use of magnesium sulphate in the treatment of eclampsia are very encouraging. It is well worth a more extensive trial by obstetricians. Chloroform and other hypnotics are, however, better than magnesium sulphate as an anti-spasmodic.

Evipan-sodium. Evipan sodium is the sodium salt of N-methyl-c-cyclo-hexenyl-methyl-barbituric acid which dissolves freely in water. It is put up in dry ampoules containing the drug in powdered form, which is dissolved in sterile distilled water to form a 10 per cent. solution. It is used intravenously either as a basal narcotic or as a general anaesthetic for minor or major operations. The dosage depends upon the individual consideration of the surgeon. The body weight is too uncertain a factor to serve as a guide. All that one has to do is to watch carefully the dosage which is producing sleep and according to the nature of the operation the dose is increased to get the desired depth of anaesthesia. In small operations 2-3 c.cm. will be sufficient; for more prolonged operations a dose of 8-11 c.cm. produces a smooth and perfect anaesthesia lasting from 20 to 35 minutes and sometimes even longer. There is usually no untoward after-effects and in no case is anything found to show that evipan has any deleterious effect on any organ. Evipan is not suitable for feeble or toxemic patients or those with cardiac and respiratory failure.

6. AGENTS THAT CAUSE SCLEROSIS OF THE VEINS

The application of injection therapy to such conditions as hæmorrhoids, varicose veins and allied lesions has recently come to the forefront. These conditions were previously treated by surgical methods which were not always successful. In surgical treatment, anaesthesia with all its dangers and complications is an important factor. Added to this is the prolonged rest in bed and consequent loss of time and money. Injection treatment is free from all these disadvantages and probably has thus given comparatively better results. The latter method of treatment has therefore been largely adopted within recent years.

A. **Hæmorrhoids.** Hæmorrhoids are quite common in people residing in the tropics. Palliative and operative treatment used to be carried out in almost all the cases. Injection treatment has now placed in our hands a safe and efficient method of treatment. The type of patient who will react best is the one whose main symptoms

are hæmorrhage with or without an associated mild degree of prolapse. Phenol 5 per cent. in almond oil or olive oil is the most satisfactory substance to inject. The aim of the method is to glue the rectal mucosa to the muscular wall and hence the injection is made high up into the rectal sub-mucosa and not into the piles itself. Quinine and urethane have been tried but these tend to produce sloughs and a brittle rectal mucosa. The advantages claimed for this method are :—

1. The method is less painful and less dangerous.
2. It is ambulatory.
3. It is less expensive in time as well as in money.
4. The incidence of recurrence is less than after operative interference.
5. The danger of the formation of a stricture, one of the common complications of radical operation for piles, is entirely eliminated.

Technique. The solution is readily prepared by melting phenol crystals over a water-bath and adding an equal volume of warm almond or olive oil. This makes a 50 per cent. solution and it may be preserved as a stock solution. The solution is sterile by virtue of its phenol content. The solution to be used is diluted before use by adding nine parts of warm almond oil.

The patient is placed in the left lateral position. Emptying the rectum is the only pre-operative preparation necessary. The speculum is inserted and a point well above the pile-bearing area is chosen. One to 2 c.c. of phenol solution is injected into the submucosa but not into a vein. Two areas may be treated every 5 to 7 days and at each subsequent treatment an area a little lower in the rectum is chosen. After 5 or 6 treatments the patient is usually cured and the pile becomes as hard as a piece of parchment.

B. Varicose veins. The treatment of varicose veins has been revolutionized by the introduction of intravenous sclerosing agents and operative interference is now practically dead. This treatment can be practised on any patients whatever their age, and it is practically universally applicable in all cases. Where the varicosity is due to some secondary complications such as a growth in the pelvis, advanced systemic disorders or deep-seated bacterial phlebitis, it is always safe to avoid giving injections. During pregnancy, due to the pressure of the enlarged uterus, varicose veins may appear in the legs. It is always better to treat these varicose veins by sclerosing agents, though some authorities have treated them by injections during the early period.

Sclerosing agents. Unlike the treatment of piles, there is no agreement as to the best solution to be used in the treatment of varicose veins. Different observers have recorded successful results with different solutions. The sclerosing agents most commonly employed to-day will be discussed below.

Quinine and urethane mixture. The mixture commonly used consists of a 13 per cent. quinine and 6.5 per cent. urethane solution, and 2 to 3 c.cm. is usually injected. The quinine is the important constituent and brings about endotheliolysis. The urethane is added for its anaesthetic effects so that the actual pain is much less. The advantage of this preparation is that it nearly always produces a thrombosis and consequently not more than 2 or 3 injections are required in the majority of cases.

The reaction induced by the quinine is a severe one, and sometimes the whole saphenous vein becomes filled with clot, following one injection only. The vein usually remains inflamed and painful for six weeks or so. Faulty technique with this solution is always attended with severe results. If the quinine escapes through the puncture and if a thin-walled vein is chosen for injection, the results may be a sloughing ulcer taking a pretty long time to heal up. General toxic manifestations are sometimes noticed.

Contraindications. General systemic diseases such as cardiac and renal diseases are not contraindications. Acute phlebitis, intermittent claudication, deep thrombosis and phlegmasia alba dolens, etc., should be avoided. During pregnancy the treatment may be carried on according to requirements.

Hydrocele and Varicocele. Injection of sodium morrhuate has also been tried in hydroceles and varicoceles. Although there is a growing opinion that injection treatment is a good method, the idea has not yet gained popularity.

7. AGENTS INJECTED INTRAVENOUSLY FOR DIAGNOSIS

Recently, a number of drugs have been introduced in medicine which are used for diagnostic purposes. These find their most important application in radiography. Sodium tetraiodophenolphthalein has been used in gall bladder radiography and uroselectan B in pyelography.

Uroselectan B is a pyridine derivative with 51.5 per cent. of iodine in close organic combination.

According to clinical trials made by Professor A. Von Litchtenberg in the Urological Department of St. Hedwig's Hospital, Berlin, the intravenous injection of the contents of one 20 c.c. ampoule is sufficient to give pyelograms which provide all the detail necessary for diagnosis.

Children must naturally be given smaller doses in view of the reduced capacity of their circulatory system.

Technique of injection. Uroselectan B is supplied in 20 c.cm. ampoules sterilised ready for use. Each ampoule contains 16 grams

of the substance dissolved in a 10 per cent. solution of invert sugar (a mixture of equal parts of dextrose and laevulose). The ampoules are warmed to body temperature in a water bath. The contents are then injected as slowly as possible into the cubital vein with an ordinary 20 c.cm. syringe.

As in the injection of any other hypertonic solutions care must be taken that the needle lies centrally in the lumen of the vein and that the injected fluid becomes diluted as far as possible by the blood stream. In this way damage to the intima will be avoided. The use of a fine needle is an advantage, provided that it is borne in mind, that the intima is more easily injured with such a needle, and particular caution is exercised to avoid this.

When it is correctly administered, the injection of Uroselectan B is very well tolerated; there need be no fear of the occurrence of venous thrombosis.

Pyelography. When only anatomical information is desired, it is as a rule sufficient to take a single pyelogram 20 to 30 minutes after the injection. In cases of calculus, displacements and similar anomalies, this method will almost invariably give the information required. If, however, a more exhaustive urological investigation is necessary, in order to demonstrate the functional efficiency and dynamics of the urinary tract, a series of exposures must be made.

The first exposure is made 10 minutes, the second 30 minutes and the third 50 minutes after injection. It has been observed, however, that in many cases when renal function is normal, the best films are obtained 2 to 5 minutes after injection. Before the second and third exposure the bladder should be emptied so that the shadows of the pelvic portions of the ureters are not obscured. In patients with considerable disturbance of renal function satisfactory pyelograms first appear not later, and may not become sufficiently clear for the purposes of demonstration, for 6 to 24 hours after the injection. If the kidney function is completely suspended, permanently or temporarily, no uroselectan B will be excreted and it will be impossible to obtain a pyelogram.

In general, care should be exercised in employing uroselectan B in patients with severely impaired liver function or with acute or chronic uraemia, all the more, as frequently no pyelogram of any value for diagnosis will be obtained. Further, it should be employed with caution in cases where the urinary disease is accompanied by severe general disease.

Cholecystography. Certain substances, when injected subcutaneously, are excreted exclusively through the biliary passage. Some of these used for testing the global capacity of the liver are opaque to x-rays

and these are employed for obtaining cholecystograms. Various substances are used for this purpose and of these the sodium salts of tetra-iodo-phenolphthalein is the most opaque to x-rays so that a smaller dose is required. Formerly, the intravenous route was adopted for this purpose, usually about 3 gm. for an adult or 0.048 gm. per kilo. body weight. Nausea and vomiting accompanied by a marked fall in blood pressure were often observed. In view of the frequency with which these toxic manifestations have followed the intravenous injection, this method of administration has been given up. Oral administration is the method of choice now-a-days and there is very little, if any, risk of provoking toxic reactions when any of the salts, either bromo or iodo, are given by mouth.

Cerebral angiography. A study of the radiological appearances of the cerebral blood vessels after injection of opaque solution into the carotid artery, is an important aid in the diagnosis of some intra-cranial growths. In view of the fact that it reveals important new anatomical and physiological findings, mention of this is made here. 'Thorotrast', which is claimed to be a stabilized thorium dioxide solution containing 25 per cent. by volume of thorium dioxide (ThO_2), along with a preservative (0.15 per cent. of methyl-p-hydroxy benzoate), is generally used for obtaining a radiogram of the intracranial blood vessels. Ten to 16 c. cm. of thorotrast is injected into the lower part of the common carotid artery and a series of radiograms at intervals of one second is taken. By this means it has been possible to display the cerebral veins and sinuses as well as the arteries. This procedure is quite safe and not attended with any inconvenience to the patient. It is, however, doubtful whether cerebral angiography has got any special advantage over ventriculography as the main accessory method available for the diagnosis of intracranial tumours.

CHAPTER IV

ACIDOSIS AND ALKALOSIS

These terms were first introduced at a period when there was no exact knowledge regarding the reaction of blood. It was thought at the time that the reaction of blood altered freely, whereas we now know that there is an elaborate mechanism at work for maintaining the reaction of blood at a constant level and that only small changes occur during life. The term acidosis has been applied to a condition in which there is an increase in the amount of CO_2 in the blood or to an increase in the fixed acid of the blood; but it has given rise to so much confusion that it is better to abandon the term altogether and to speak of a decrease in the alkali reserve of the blood. Sellard defined acidosis "as a diminution in the reserve supply of the fixed bases in the blood and other tissues of the body, the physico-chemical reaction of the blood remaining unchanged except in very extreme conditions. The definition should not be limited to the carbonates alone, but should include other fixed bases of the body; likewise the changes should not be limited to the blood, but should include the other tissues as well." Acidosis, therefore, really means some change in the blood which, if uncompensated, would alter the reaction of blood towards the acid side and alkalosis means that which would alter it towards the alkaline side.

It is very easy to change the reaction of a fluid like water, which only contains H and OH ions. Blood however is a very complex substance, and the hydrogen-ion concentration of blood is perhaps one of the most constant things in nature. In spite of the fact that a number of factors, such as production of acid from metabolic processes and muscular exercise or draining of acid from blood during gastric secretion, etc., are constantly tending to alter the reaction of the blood, the regulating mechanism is wonderfully efficient in keeping the same constant. This is only possible because blood contains a number of sub-

tances, such as acid and alkaline phosphates and sodium bicarbonate, which together with the hæmoglobin and protein act as a powerful 'buffer' and prevent the reaction of the blood being easily changed. Further, other regulating mechanisms are at work, since urea can split up into carbon dioxide and ammonia, the former can be excreted by the lungs, while the latter can be used to neutralise any acid. The kidneys can excrete acid or alkali salts which may be in excess, and thus help to maintain the acid base equilibrium constant. Henderson considers carbonates of the blood as the first line of defence against acidosis. A second line of defence is the capacity of the kidneys to excrete an acid urine from a neutral blood; they remove the acid phosphates and save the base. A third line of defence is furnished by the proteins. Proteins can combine with appreciable amounts of either acids or alkalis without undergoing any marked change in reaction. Another line of defence is ammonia, which the body produces, whenever there is a demand, at the expenses of urea.

Briefly the various factors that are constantly at work to maintain the acid base equilibrium can be grouped under the following heads;—

1. The intrinsic property of blood.
2. The renal factor.
3. The metabolic factor.
4. The respiration.

1. The blood normally contains some buffer salts which give it the property of maintaining its reaction always constant. The phosphates in forms of Na_2HPO_4 or NaH_2PO_4 play a very important role in the buffering action. The addition of acids or alkalis, results in the formation of compounds which do not give free H or OH ions in solution and consequently the reaction of the blood is not influenced. Sodium bicarbonate also plays a similar part, weak H_2CO_3 is liberated when it is acted on by an acid and a neutral salt is formed. The H_2CO_3 is quickly excreted in form of H_2O and CO_2 . The buffer substances present in the blood constitute the true alkali reserve and it is the alkali reserve that undergoes the chief changes in

disease. It is usual to estimate alkali reserve in the form of sodium bicarbonate and a measure of it would indicate the extent of the acid condition, a low figure pointing to a serious state. Depletion in the alkali reserve precedes a rise in the hydrogen-ion concentration and hence, is a valuable indication for treatment.

2. The renal factor. If the carbonates in blood were the only method of defence of the body the organism would die from acidosis as soon as the bicarbonate was depleted by the excretion of neutral salt through the kidney; every molecule of acid would rob the body of a molecule of bicarbonate. The second mechanism comes into play and that is the remarkable power of the kidney to secrete urine of widely varying reaction from the blood of a constant hydrogen-ion concentration. The kidneys thus remove acid phosphates and some base with each molecule of acid phosphate that they excrete. Thus although alkali is eliminated in the urine, it is much less than would be the case without this specialised kidney activity. The method by which the sodium bicarbonate reserve of the body is renewed may be expressed by the following:—

$\text{Na}_2\text{HPO}_4 + \text{HCl} = \text{NaCl} + \text{NaH}_2\text{PO}_4$ the hydrochloric acid is neutralised and the sodium chloride and acid sodium phosphate are excreted by the kidneys.

the acid sodium phosphate is excreted. Therefore one of the renal functions would be to keep the ratio $\frac{\text{NaH}_2\text{PO}_4}{\text{Na}_2\text{HPO}_4}$ constant by excreting one or the other as the case may be. In this manner the kidneys will excrete the hydrogen ion.

3. The metabolic factor. The metabolism of protein, carbohydrate and fat causes the appearance of non-volatile acids as intermediate products of metabolism, which under normal condition are oxidised to form CO_2 and H_2O . The protein nitrogen is first deaminated in the liver, and an oxyacid and ammonia are set free. Normally the greater part of ammonia combines with CO_2 and water, forming ammonium carbonate, which, in turn, is converted into urea and eliminated as such.

Any excess of non-volatile anions over kations is adjusted by the kidney, which usually secretes urine of high acid reaction.

4. **Respiration.** The physiology of the respiratory centre is most interesting, for when the amount of acid increases in the body, there is a quick stimulation of these centres, with the result that more CO_2 is thrown out and the fixed acid of the blood is prevented from assuming large proportions. The respiratory centre is extraordinarily sensitive to the slightest alteration in the reaction of blood towards the acid side, so that an increased production of carbon dioxide in the tissues and the resultant slight excess in the blood is answered by an increased ventilation of the lungs. It appears that the body uses this weak volatile acid for fine adjustment of the blood reaction, a condition of acidosis being accompanied by washing out of acid in form of CO_2 , while an alkalosis is compensated by the retention of this substance.

In clinical practice the danger in disease lies in the exhaustion of the alkaline reserve in the blood and this may be the result of (1) increase in the fixed acids present in the blood after violent muscular exercise or in diabetes and renal diseases, (2) reduction in the fixed acid, (3) interference in the excretion of carbon dioxide, (4) excessive excretion of carbon dioxide in certain types of pneumonia, (5) non-gaseous acidosis in disease.

The measure of the degree of acidosis consists in the estimation of:

1. Lowered carbon dioxide combining-power of the blood.
2. Lowered alveolar carbon dioxide tension.
3. Degree of affinity of hæmoglobin for oxygen.
4. Reduced alkalinity of the blood.
5. Increased hydrogen-ion concentration of the blood.
6. Increased intensity of urinary acidity.
7. Retention of alkali in the body.

Non-gaseous acidosis. The metabolism of proteins, carbohydrates and fats, produces non-volatile acids, which normally are oxidised into CO_2 and H_2O , whilst proteins are excreted as urea. The kidneys excrete urine with strong acid reaction and in this way eliminate the excess of non-volatile anions. This state of affairs may be disturbed in disease, resulting in reduction of alkaline reserve and reaction of the

blood shifting towards acidity. This occurs (1) when there is failure of respiration and circulation and the supply of oxygen to the tissues is deficient. (2) In diabetes where the cell metabolism for carbohydrates and fats becomes abnormal. In injuries of the liver also acidosis is produced. (3) In kidney disease fixed acids accumulate in the body.

Administration of large doses of calcium chloride and ammonium chloride produces a reduction of alkaline reserve in the blood. The ammonium chloride is changed into urea by the liver liberating HCl and H_2O . The calcium ion of calcium chloride forms calcium carbonate in the gut which remains unabsorbed and the excess of chloride is absorbed which produces acidosis. The onset of acidosis is accompanied by diuresis.

A large amount of partially oxidised products of metabolism are produced after a short period of violent physical exercise. After half a minute of violent exercise a subject can incur an oxygen debt of 16 litres and the oxidation of the products of partial catabolism after a debt of this magnitude take more than an hour to complete. Such oxygen debt corresponds to about 70 gm. of lactic acid, a quantity that would produce an average concentration of 0.12 per cent. lactic acid in the body. Not more than 0.1 to 0.2 per cent. lactic acid appears in the blood in such cases and probably most of the lactic acid is neutralised temporarily by the muscle protein. In uncompensated cardiac disease the most striking feature is the inability to oxidise any excess of lactic acid produced as a result of exercise.

The chief symptom of acidosis is dyspnoea and in addition to this there are usually symptoms due to the particular defect that caused acidosis.

Acidosis in diabetes. The defective oxidation of the fats in diabetes results in the formation of β -hydroxybutyric acid, aceto-acetic acid and acetone. The interaction of these organic acids with the sodium bicarbonate of the blood, results in the taking up of sodium by the acids and the setting free of CO_2 , thus robbing the body of its alkaline reserve. Allen states that fasting checks the acetone formation and that alkali holds no more than an adjuvant position. There is little need for the use of sodium bicarbonate in the treatment of diabetic acidosis at the present time, as insulin is almost a specific.

Acidosis in nephritis. The kidneys secrete daily an amount of acid corresponding to 20–50 c.cm. of normal acid. This quantity is insignificant when compared to the quantity of acid

excreted by the lungs as CO_2 , for the lungs excrete about 1500 gm. of CO_2 daily. The acid secreted by the kidneys however is non-volatile which cannot be excreted by the lungs, and if this acid was retained in the body, it would rapidly exhaust the alkaline reserve of the blood. The urine contains phosphates which act as buffers and prevent the acid excreted, producing a degree of acidity which would be irritant to the bladder. The reaction of urine varies from pH 5 to pH 8. Many cases of chronic renal diseases show a more or less pronounced acidosis with marked nitrogen retention. Cases of acute nephritis may occasionally show a severe acidosis. Favourable results are obtained in these cases by the administration of alkali.

Acidosis in children. Acidosis has been found in many cases of severe diarrhoea in children. Those, not attended with ileocolitis, show only a moderate increase in acetone bodies and a deficient excretion of acid phosphate by the kidneys, while with ileocolitis the amount of acetone bodies is very large. The administration of sodium bicarbonate will in most cases bring about a cessation of symptoms of hyperpnoea but a cure can hardly be effected by this treatment.

Acidosis as a result of anæsthesia. The administration of anæsthesia results in a lowering of the CO_2 combining-power of the blood and consequently there is a decrease in the alkali reserve. The initial acidosis of anæsthesia is an uncompensated one, since there is an immediate fall in the pH which precedes the fall in total CO_2 . Hence there is a grave risk run when cases of severe diabetes or nephritis with low figures for the CO_2 are operated on under general anæsthesia. A preliminary administration of sodium bicarbonate increases the alkali reserve and it also leads to higher values for this factor at the conclusion of the anæsthetic.

A condition of 'acidosis' or diminished alkali reserve in the body has been known to occur in different diseases. The diseases in the tropics in which this condition has been recognised are cholera, kala-azar, blackwater fever, malaria, yellow fever, trypanosomiasis and heat stroke.

Reaction of blood in kala-azar. There is very little change in the pH of the blood in this disease, the change being slightly towards the alkaline side. More accurately speaking, it may be stated that in kala-azar the hydrogen-ion concentration of the blood is usually about normal, but the buffer action is reduced.

Acidosis in malaria. As far back as 1895 Steindler and Limbeck reported a diminution in the alkalinity of the blood in cases of malaria. It has now been definitely found out by Sellard's 'bicarbonate tolerance test' that the reaction of blood in malaria points to a moderate degree of acidosis. No marked relationship, however, can be made out between the amount of acidosis present and the intensity of the signs and symptoms.

Acidosis in cholera. The most constant feature in cholera is a great reduction in the alkalinity of blood. From a normal of about $\frac{N}{25}$, it falls to as low as $\frac{N}{60}$ to $\frac{N}{80}$, and in fatal cases even lower. There is also a retention of phosphates in the blood. Our knowledge of this characteristic feature has greatly reduced the mortality rate from this complication. The acidosis, if it has not been allowed to proceed to a fatal degree, can be combated by use of sodium bicarbonate solution for intravenous injection.

Alkalosis. Reduction in the fixed acids can be produced by persistent vomiting, which causes loss of HCl. The alkaline reserve is increased and there is a tendency to alkalosis. A similar condition can be produced by giving large doses of sodium bicarbonate which increases the carbonate content of the blood.

Hyper-ventilation of the lungs causes the washing out of CO_2 from the blood, and a consequent shifting of the reaction of the blood towards alkaline side. Inhalation of irritant gases also produces this condition and it also occurs during hyper-ventilation produced in the initial stages of ether anaesthesia. Alkalosis also occurs in hysterical hyperpnoea.

The symptoms of alkalosis are headache, nausea and vomiting, dizziness and weakness. In severe cases of tetany,

semicoma and convulsions may occur. Tetany is probably produced owing to the fact that increased alkalinity reduces the dissociation of calcium salts and therefore reduces the concentration of ionic calcium present in the blood. It should be realised that alkalosis is a serious condition and the physician should bear in mind when prescribing large and frequent doses of alkalies.

Treatment of acidosis and alkalosis. The treatment of acidosis must be directed chiefly to the care of the derangement of functions that caused the condition, but the actual symptoms can be relieved by intravenous injection of sodium bicarbonate.

The simplest treatment for alkalosis is the inhalation of CO_2 . The calcium content of the blood can be raised by the administration of para-thyroid extract or by the administration of calcium salts by mouth or intravenously.

CHAPTER V

CHEMOTHERAPY

Historical and General. The search for a specific remedy to cure a specific disease or diseases is as old as the art of medicine. From very ancient times physicians and healers have worked to attain this ideal, and various remedies have been suggested and tried in the treatment of various diseases. In former days chance was the only foundation of their investigation, and empiricism dominated the therapeutic investigation in the treatment of disease. In fact, empiricism still dominates the scientific search for specific remedies and it has not been altogether unsuccessful. There are the examples of cinchona for malaria, salicylates for rheumatic conditions, ipecacuanha for amœbic dysentery, all of which were used empirically centuries ago. The number of specific remedies is unfortunately very small. The modern scientific line of investigation of specifics for diseases is known as 'chemotherapy.'

Before entering into any details it will be convenient to see what the meaning of the word chemotherapy in the modern sense of the term implies. It has been observed before that the use of certain drugs in specific diseases is as old as the art of medicine. The work of scientists like Pasteur, Koch, Lister and others advanced our knowledge of diseases to a considerable extent and the discovery of microbes as a causative agent for infectious diseases, with the almost simultaneous observations about the action of chemicals on these microbes, indicated that the long-maintained theory of finding specific drugs for specific diseases was possibly about to materialize. It was soon discovered that this idea of treating diseases does not hold good in practical therapeutics. Although certain chemicals such as phenol, and mercuric chloride, exerted a very powerful action on bacteria, their action on the body cells was equally marked and the chemicals highly toxic to bacteria were also toxic to the body cells. Their employment in practical therapeutics is, therefore, often not possible.

The discovery of diphtheria antitoxin and its successful use as a curative and prophylactic measure against diphtheria, stimulated the idea of finding antibodies for all bacterial diseases through natural agencies, but it was soon realised that this theory does not hold good.

for the body does not develop immunity in the case of all diseases as it does in the case of diphtheria. It was then thought that rapid advance in synthetic chemistry might give that power into the hands of man which is absent in nature, that it might be possible to evolve certain synthetic products which would be very toxic to the parasites and least harmful to the body cells.

At about the same time as this idea was taking firm root in the minds of scientists, Laveran and Mensil (1902) attempted to cure experimental trypanosomiasis in small laboratory animals with various chemical reagents. Arsenious acid was at that time used in the treatment of animals naturally infected with trypanosomes, and these workers tried this drug as well as many other chemicals for treating this disease. They met with results which did not materially advance the treatment of trypanosomiasis, but their method of investigation was readily accepted for studying the parasitocidal action of a particular drug in relation to its toxicity. Simultaneously Ehrlich was engaged in the study of dye stuffs and their effects upon the cells, and the experimental production of trypanosomiasis in laboratory animals gave an impetus to his studies. This work led to the discovery of the curative action of 'trypan red' in mice experimentally infected with *T. equinum*. After this followed trypan blue, afriol violet and several other synthetic coal derivatives.

Immediately following this work, Thomas (1905) found that atoxyl in combination with trypan red exerted a curative effect in laboratory animals artificially infected with different species of trypanosomes. Ehrlich had tried the effect of atoxyl on trypanosomes *in vitro* before this, but as the trypanocidal activity of this compound was not found to be marked, an attempt to try atoxyl *in vivo* was not then made. Thomas' work attracted Ehrlich's attention and he, in collaboration with Bertheim, after a careful study of the chemical structure of atoxyl considered the possibility of obtaining a large number of chemical substances from this compound which were lower in toxicity but higher in trypanocidal activity. This work eventually led to the synthesis of salvarsan and definitely established the modern science of chemotherapy as a branch of pharmacology.

Shortly after the discovery of atoxyl as a trypanocidal agent, experiments were conducted with spirochaetal infections. It was shown that certain compounds of arsenic, having no spirochaeticidal action *in vitro*, have marked curative properties in spirochaetal infections *in vivo* especially those of relapsing fever in mice and spirillosis of chickens.

Definition and scope of chemotherapy. Although very limited in its original sense, the word has a most extensive application as it now includes both the treatment and prevention of disease by chemical agents which inhibit or destroy the para-

sites without producing any marked effect upon the body cells. Before entering into a discussion about the definition of the word 'chemotherapy' it is essential to understand some of the terms used by Ehrlich, the father of modern chemotherapy, and to consider some of the salient features of the principles of chemotherapy which have a direct bearing on the experiments conducted.

As has been stated before, the discovery of germicidal properties of certain chemicals at one time led investigators to imagine that those chemicals which exerted a marked toxic effect on the specific organisms can be used in the treatment of the disease. It was soon realised that this is true to some extent in local lesions only, and the application of the theory in the treatment of systemic infection is dangerous. Cholera vibrios are readily killed by perchloride of mercury but it is impossible to cure a cholera patient by this drug, for the dose which is necessary to destroy the vibrios in the gut is distinctly toxic to the host.

In considering the principles of chemotherapy therefore two main points will have to be taken into consideration. In the first place, the action of the chemical agent on the parasite should be considered. Some substances have a special affinity for a special kind of parasite and this Ehrlich designated as *parasitotropy* or *parasitotropism*. The special and selective affinity for the chemical agent may be confined to one species of parasite only—*monotropism*, or to several species—*polytropism*. It is not, however, essential that the parasitotropism should be synonymous with the parasitocidal activity of a chemical agent. Atoxyl, as we have already observed, is not strictly parasitocidal *in vitro* but still it exerts a powerful action on the growth and activity of trypanosomes *in vivo*.

The second point which should be considered is the special affinity of chemical agents for the body cells. This Ehrlich termed as '*organotropy*' or '*organotropism*' and modern chemotherapy aims at finding substances which are highly parasitotropic, while possessing the least affinity towards the body cells, *i.e.*, very low organotropism. Diphtheria antitoxin is ideally suited to serve as an example of what a chemotherapeutic

remedy should aim to be. It has a marked action on the *C. diphtheriae* while it exerts little or no action on the body cells. It is, however, difficult to find chemical substances which will have a potent action on the parasites and at the same time have little or no action on the body cells.

Chemotherapy only requires the proportion of parasitotropism and organotropism to be present to such an extent as to allow the chemical agent to be useful in practical therapeutics. The organotropic effect may not be entirely absent, but it should not make the substance toxic and dangerous. To express the relation between organotropism and parasitotropism, Ehrlich coined the phrase '*chemotherapeutic index*.' It is the ratio between the maximum tolerated dose per kilo. of body weight and the minimum dose per kilo. of body weight required to destroy the parasites in the body. The higher is this ratio the greater is the applicability of the compound in the treatment of disease. Kolmer illustrates this ratio by a concrete example: Arsphenamine by intravenous injection is generally borne by white rats in doses of 0.120 gm. per kilogram of body weight for an indefinite period; 0.140 may kill it in a few days. The former is therefore the M. T. D. (maximum tolerated dose). When administered to rats infected with *T. equiperdum*, the smallest dose per kilo. capable of completely eradicating the infection may be 0.004 gm., M. E. D. (minimum effective or curative dose). The results are expressed as follows:—

$$\text{Chemotherapeutic index} = \frac{\text{Maximal tolerated dose per kg. } 0.120}{\text{Minimal curative dose per kg. } 0.004} = 30$$

This chemotherapeutic index, however, depends upon a number of factors, *e.g.*, the animal experimented upon, the strain of infective organism used, and therefore its value is not constant.

The nature of the phenomenon of organotropism and parasitotropism is still undetermined. The selective affinity of drugs for certain cells only is well known in pharmacology. It is known that strychnine has a special affinity for nerve cells, especially the anterior horn cells of the spinal cord and the narcotics have a special affinity for the fat-like substances. Why these substances have special affinity for a particular kind of cells is still not clear. The nature of parasitotropism and organotropism is suggested to be the same as the phenomenon of special affinity of strychnine for nerve cells and may be purely chemical.

From the discussion given above it will be seen that the requirements of a modern chemotherapeutic remedy are a chemical agent which is highly parasitotropic, least organotropic and which will act in such a way as to eradicate the causative organism from the body of the host without damaging the tissues to any appreciable extent.

Various definitions of chemotherapy are given from time to time and Kolmer gives one which is used in the widest sense of the term and which includes both the prevention and treatment of a bacterial or protozoal disease with a chemical agent. "Chemotherapy may be defined as the prevention or treatment of disease by chemical disinfection or inhibition of the parasitic causes without marked or serious toxic effects." It is that branch of the science of biochemistry which deals with the therapeutic properties of certain chemicals in the curative and prophylactic treatment of parasitic diseases.

The chemical agent may be natural or synthetic. Thus quinine is as much a chemotherapeutic agent as arsphenamin. Location of the parasite does not affect the definition in any way. The parasite may be in the blood, in the lymph, in internal organs or tissues or on the external surface (skin and mucous membrane). Thus the term chemotherapy in the modern sense includes the treatment of syphilis by arsphenamin, the treatment of hookworm by carbon tetrachloride, the treatment of pneumococcal conjunctivitis by optochin or the treatment of ringworm with sulphur, the only essential factor is the complete routing or crippling of the parasites, no matter what their nature and location may be, without seriously damaging the cells of the body.

THEORIES OF PARASITOTROPISM AND ORGANOTROPISM

Side-chain theory. Ehrlich applied the same theory to explain parasitotropism and organotropism as he did to explain the theory of immunity. Kolmer gives the following extract from Ehrlich's Harben lectures.

"I also wish to lay special stress upon my view that the drugs are attracted by and bound to the protoplasm molecule by certain atom groups. I am inclined to look upon this as somewhat analogous to the binding of the toxins and of similar protein bodies. Yet on the other hand, there are fundamental differences between the two. For, as I have always insisted, the mode of binding the toxins is peculiar in so far as it is the result of a certain kind of assimilation which obviously consists in a process of a more or less synthetic nature. These toxin-receptors which produce immunity are bodies of a more independent character, and appear to be especially destined for purposes of assimilation. This high degree of independence is evidenced

by the fact that, in conformity with my side-chain theory, these receptors are very easily reproduced by the cell in excessive numbers, and after being separated from the cell, find their way into the blood.

I have now formed the opinion that in like manner a part of the chemically defined substance is attached to the cell by groups corresponding to these receptacles; these atom groupings I will distinguish from the toxin receptors by the name of 'chemo-receptors.' This view is more practically supported by the fact that an atoxyl-fast strain of trypanosomes is also resistant to a number of substances related to atoxyl, but otherwise showing widely different chemical characteristics. Evidently, therefore, the arsenic acid radical here represents the point of attack which is common to this series of substances. These 'chemo-receptors' must, however, be regarded as of a simpler structure than the toxin receptors. They do not show a similar degree of independence, nor can they be thrown off into the blood. The number of such chemo-receptors for poisons which trypanosomes possess represents the number of points of attack. By means of the resistant strains we can count off, one by one, these groups that are 'open to attack.'

This theory explains the affinity of a chemical agent or a drug for a parasite or a cell by supposing that there are certain special receptors on the cells to which these compounds become attached. Ehrlich's original work on the effect of various dyes and arsenicals on infective organisms, especially trypanosomes and spirochaetes, lent strong support to his hypothesis. According to him, a chemical agent cannot exert its action on the parasites, unless fixed by suitable chemo-receptors of the cells of the parasites. When arsenic or any other drug is administered, they are presumed to carry certain side-arms which are anchored to the special receptors of the cells of the organism. These side-arms have greater affinity for the receptors of the cells of the parasites than those of the tissues of the host, thus having a parasitotropic action with the least organotropic effect.

Chemical view. Although little can be said against Ehrlich's well-supported hypothesis, Kolmer is inclined to believe that it has prevented a chemical theory being worked out properly, and absence of a well-directed research in this line has considerably curtailed the rapid advance of chemotherapy in modern scientific direction. He is of opinion that the phenomena of parasitotropism and organotropism are purely chemical or physico-chemical in nature. He mentions Meyer and Goethliel's suggestion that arsenic produces its toxic effects by reacting with a substance which is present in the protoplasm in small amounts. Voegtlin and his co-workers have brought forward experimental data suggesting that the trivalent oxides of arsenic are specific poisons for the SH group of glutathione and possibly other SH compounds in the protoplasm of the cell, with a consequent sup-

pression of vital functions, which may explain the toxic and therapeutic effects of organic arsenicals like arsphenamin.

It will however be noted that the SH group in the protoplasm is present in the parasite as well as in the body cells. The special toxicity for the parasite is, therefore, explained by Voegtlin and his associates as being due to the difference in the absolute amount of SH groups in the protoplasm of the two, so that exposure to a certain concentration of arsenoxide will kill the parasite, while the cells of the animal will survive. They give a very plausible suggestion that those infective diseases, whose causative organisms require a considerable amount of SH group for their nutrition, will be benefited by arsenic. Voegtlin propounded an interesting theory depending upon the action of oxidation and reduction. He believes that the parasites maintain their oxygen by constantly exhibiting a reducing action on their surfaces. The body of the invaded host contains a protective substance which lies chiefly in the protein of serum. The colloidal particles of this protective substance are always striving to increase their surface oxygen which appears in the form of hydroxyl; if the protective substance has an excess of OH (hydroxyl) then it will neutralise the H-ion present on the surface of the parasite. This will therefore kill the parasite because it will not be able to maintain its H-ion the surface.

At present it seems justifiable to conclude that several factors are at work in producing the various parasitocidal effect of drugs. Cushney has summed up the present position very ably. He states that "these views have all been supported by a certain amount of evidence, and there is every reason to believe that these physical properties are important factors in the action of some drugs. But it is equally obvious that no one of them will explain the whole of pharmacological action, and there is reasonable doubt whether the whole of the physical characters taken together will suffice for this. From the present confusion the only legitimate conclusion seems to be that the activity of drugs depends on a large variety of factors, and that pharmacological action cannot be brought under any one law, either chemical or physical."

Factors influencing the action of drugs upon the parasites and the body cells. Attention has already been drawn to the different results obtained from *in vitro* and *in vivo* experiments. There is therefore some profound change occurring in the body which gives this divergence in the *in vitro* and *in vivo* experiments. The changes will mainly depend on the channels of absorption, for a variety of chemical and physico-chemical actions takes place before the drug is distributed through the body to act on the parasites it is meant to destroy.

After oral administration, hydrolysis, emulsification, saponification, etc., occur in the gastro-intestinal tract before the drug is absorbed into the circulation. After absorption, the detoxicating properties of

the internal organs, especially the liver, play an important part in the modification of the drug. The changes that occur after an intravenous injection are also important for, as the drug is directly introduced into the circulation, phenomena of lysis, agglutination, precipitation of proteins, etc., may occur. Important changes of oxidation and reduction may occur and a new compound may be evolved after combination with certain cellular constituents in the body.

After absorption the chemical agent is distributed in the body, not uniformly but selectively, and the aim of chemotherapy is to concentrate the agent in those tissues where the parasites are supposed to be numerous. The concentration in the tissues depends upon the method of administration, dose, elimination and the changes that occur in the body cells. Special affinity of a particular tissue will also determine the concentrations of the agent in the tissues.

Acquired or natural tolerance to the action of drugs is a well-known phenomenon. Certain individuals have got the power of tolerating large doses of poisonous drugs without showing toxic effects. In the case of habit-forming drugs, *e.g.*, alcohol, cocaine, nicotine, etc., the tolerance is probably psychic, developed as a result of the nervous system getting adapted to continued use. Other cases may be due to increased destruction of the poison, as is found with opium and its alkaloids, or the result of diminished absorption or increased elimination. Another conspicuous instance of tolerance is found in the formation of antitoxin. Such antitoxin formation is the result of repeated administration of foreign proteins, either animal or bacterial. Antitoxin formation has also been observed with certain glucosides, snake venom, poison ivy, etc.

DRUG RESISTANCE

It was not, however, known till very recently that parasites too acquire tolerance to drugs. This tolerance in parasites to withstand the destructive action of a chemical agent is known as *drug fastness*. A huge literature has since been piled up regarding the nature of drug fastness in various parasitic infections, such as trypanosomiasis, spirochaetosis, and from this standpoint the treatment of infectious diseases is of great interest in order to decide whether a particular remedy does or does not produce resistance in the causative organism. Ehrlich and his collaborators (1909) recorded interesting observations on the

drug fastness of trypanosomes. Working with nagana-infected mice they found that after feeding the mice with para-fuchsin, the parasites disappeared from the peripheral blood. After some time they reappeared, and by continuing the feeding it was observed that successive administration of the dye became less effective in removing the parasites from the peripheral circulation. Then a time was reached when the time of banishment of the parasites from the circulation became progressively shorter until the drug entirely failed to rid the blood of the organism. After transference of the strain to a healthy mouse it was found to be uninfluenced by the action of para-fuchsin. The drug had therefore produced in the organism a heightened resistance to withstand the otherwise fatal concentrations of the same drug. This interesting discovery was further supplemented by a series of experiments to determine the specific character of fastness acquired by trypanosomes with doses of various drugs. Arsacetin in doses insufficient to cure the animal of the infection with trypanosomes, developed in mice a strain of organisms which could not later be influenced even by maximum tolerated doses of the drug; the strain thus seemed to have acquired a 'fastness' to arsacetin. But it could be influenced by a more potent arsenical preparation, *e.g.*, arsenophenylglycine, which subsequently produced a further strain of resistant trypanosomes on repeated treatment with subeffective doses of this compound. This work of Ehrlich and others brought to light some very interesting facts about the specific character of drug fastness. It was at the same time observed that a strain of an organism resistant to the action of arsenic, may or may not show resistance to antimony preparations, *e.g.*, tartar emetic, but it never exhibited any fastness to trypanocidal dyes of the tetrazo series, *e.g.*, trypan red, trypan blue, or to triphenyl methane dyes (para-fuchsin). On the other hand, strains resistant to trypan red were also resistant to trypan blue, but not to the triphenyl methane dyes or to the arsenical compounds.

This characteristic resistances of the different micro-organisms to the action of various drugs has been observed not only in the case of trypanosomes but in various other infections. Thus Massart (1889) succeeded in making certain flagellates resistant to higher concentra-

tions of sodium chloride. Davenport and Neal (1896) were able to produce resistance to mercuric chloride and quinine in a protozoon (*Stentor coeruleus*) by exposing it for several days to the action of sublethal doses of those drugs. Danysz (1900) was successful in producing arsenic resistance in *anthrax bacilli* by cultivating them in a medium containing As_2O_3 . Morgenroth and Kaufmann (1912) found the pneumococci to have acquired resistance to ethyl hydrocupreine (optochin) when they were subjected to repeated sublethal doses. Shiga (1913) produced a strain of resistant cholera vibrio by cultivating the organisms *in vitro* in different concentrations of dyes, such as methylene blue, tryflavine, etc. The resistance of the vibrio gradually increased till it reached a maximum. Such resistance was, however, lost if the vibrio were cultivated in a medium not containing the dyes. Haedel and Baerthlein (1913) noted the resistance of typhoid and paratyphoid bacilli to quinine. Englin (1918) reported the resistance of *Plasmodium malariae* to quinine. Neuschlosz (1920) working with *Paramacium caudatum* was successful in producing strains of this organism resistant to the action of quinine, arsenic, antimony and various dyes.

The phenomenon of drug resistance has been observed by various workers both in experimental studies and clinically in the treatment of infectious diseases, and there is very little doubt that it does occur. The nature of this resistance is but imperfectly understood. It is one of the most complex biological phenomena that has been observed in the reaction of the living organisms to the action of chemicals.

The nature and mechanism of drug-resistance. It is very difficult to say at present why and how a certain strain of organism acquires the character of withstanding otherwise lethal doses of a poisonous drug. This resistance may be a character of the causative organism or it may reside in the tissues of the host. The idea that the resistance to the action of a drug is not a character of the infective organism but of the invaded host was first formulated by Breinl and Nierenstein, and by Mesnil and Brimont, who, working with trypanosomes, concluded that a strain of trypanosomes made resistant to the action of atoxyl in one species of host (mice) did not exhibit that resistance when transferred to another host (rat). But such a theory is no longer tenable as it has been established that a strain of trypanosomes in mice made resistant to an aromatic arsenical compound is similarly resistant when transferred to rats or rabbits and *vice versa*.

The question now arises as to what this peculiarity can be attributed. Ehrlich, in his side-chain theory, has postulated the existence of a large number of chemical groups in the protoplasm of the organism.

Each one of these chemo-receptors is supposed to fix a molecule of the drug by virtue of chemical combination, and according to this view, the influence of the host is negligible. He supposes that the phenomenon of resistance of a strain of organism to a particular group of drugs is due to a lower chemical affinity of the specific receptors for those drugs to which the strain has become resistant. Voegtlin and his co-workers in America have doubted the adequacy of this theory. They have experimentally proved that the action of arsenical compounds in trypanosomiasis is dependent on the active participation of the host. The parasitocidal effectiveness of chemical agents, such as the arsenicals, will therefore be determined to a considerable extent by the power of retention of the drugs by the host. They are of opinion that Ehrlich's theory is far too simple to explain the complicated phenomenon, considering the fact that a resistant strain of trypanosomes can be made to withstand 250 times as much reduced trypanamide as does the original strain. Voegtlin has therefore devised a theory which postulates that trypanosomes acquire resistance to arsenic by virtue of the development of an excess of sulph-hydryl compounds, which enable them to detoxicate the poisonous effect of arsenic. Kolmer also supports a similar theory and explains the phenomenon on the basis of a chemical interaction between the drug and the parasite. He believes that natural tolerance is due to the absence in the protoplasm of the cell of the parasite of a chemical constituent capable of interaction with the drug administered, or the presence of a substance which unites with the drug and renders it inert.

Such a theory has, however, been criticised by Yorke (1931) who has shown that, contrary to the hypothesis of Voegtlin, the arsenic-resistant trypanosomes do not absorb any aromatic arsenicals even though these may be present in concentration rapidly fatal to the normal strain of parasites. By suspending normal trypanosomes in a nutrient medium containing 1 in 12,000,000 of reduced trypanamide for one hour at 37°C., it was found that all the drug was taken up by the parasites, while under the same condition the resistant strain did not absorb any drug at all.

Yorke is inclined to believe that the phenomenon may be explained in a different way. The adoption of the various micro-organisms to changed environments may be the result of natural selection, i.e., a gradual dying out of the more sensitive individuals and the survival of the more resistant ones. This is rather difficult to prove so far as drug resistance is concerned. But it must at the same time be admitted that different individuals of a strain differ in respect of age, and hence it is very likely that these may possess *per se* different degrees of viability. It is, therefore, justifiable to imagine that successive generations of a given strain possess greater power of resist-

ance than the original one. This theory, however, is not wide enough to explain the resistance that may be made to develop in some to an enormous extent. Another factor that may be working is a process of mutation or gradual adaptation in some or all of the parasites, whereby the successive generations acquire drug resistance, as a result of the stimulus of frequent exposures to sublethal concentrations of the drug. This process of mutation may be aided in some cases by a process of natural selection as well.

Drug resistance, specially in the case of trypanosomes and also in spirochaetal infection, is apparently a stable phenomenon independent of the kind of host in which the parasites may reside. Morphologically also the strains of resistant parasites are indistinguishable from the non-resistant ones. By repeated exposures to non-fatal concentrations of a particular drug they develop a certain characteristic by which no drug is absorbed by them, while the same concentrations would be fatal to the untreated organisms.

Drug resistance in trypanosomiasis. It has been known for a long time that trypanosomes which have survived the first effect of an arsenical compound, can later on withstand the effect of larger doses. Repeated arsenic medication produces in successive generations, a strain of parasites resistant to the action of arsenic. This has also been recognised clinically in sleeping sickness. The difficulty of curing trypanosomiasis in some cases with arsenical preparations is well known. In the treatment of Rhodesian sleeping sickness, doses of tryparsamide have been found to be ineffective in curing the infection, while maximum tolerated doses of Bayer 205 have been seen to produce a complete cure. This ineffectiveness of certain compounds in trypanosome infection is more readily seen in cases treated with insufficient doses of a particular drug, giving thereby a chance for the parasites to acquire a resistance to a particular chemotherapeutic agent.

The resistance of the trypanosomes against various arsenicals and dyes was first recognised by Ehrlich in 1908, since when many interesting phenomena have been brought to light in connection with the drug-fastness of trypanosomes. Voegtlin and others (1924) showed that arsenoxide (3-amino-4-oxyphenylarsenious oxide) was less effective in influencing the resistant strains of trypanosomes than the normal

strains when exposed to the same concentrations of arsenoxide. The behaviour of the parasites has also been found to differ with different preparations of arsenic. Arsphenamin, which is retained in the body after continued administration, can produce a sufficient degree of arsenic-resistance in a relatively short time. Other arsenicals such as atoxyl, arsacetin, tryparsamide and similar pentavalent compounds, which are rapidly excreted, take a much longer time to do the same. Yorke (1929) developed a technique of keeping alive suspensions of trypanosomes to study the trypanocidal property of various antimony and arsenic preparations. His strains of *T. rhodesiense* made resistant to atoxyl and acriflavine were tested *in vitro* and *in vivo* on (a) aromatic arsenical compounds such as atoxyl, tryparsamide, holarsol, arsacetin, reduced tryparsamide, reduced arsacetin, and novarseno-billon; (b) aromatic antimonials, such as stibosal and stibenyl; (c) the non-aromatic antimony and arsenic compounds, such as tartar emetic and sodium arsenite; (d) acriflavine and Bayer 205. Both the strains were found to be resistant to all the aromatic compounds of antimony and arsenic and to acriflavine but not to the non-aromatic compounds or to Bayer 205. It was also found that *in vitro* the resistance of the treated strains was much heightened compared to the normal ones. A concentration of 1 in 100,000,000 reduced tryparsamide killed a normal strain of *T. rhodesiense* within twenty-four hours, while under similar conditions a resistant strain withstood a solution of 1 in 400,000.

As the trypanosomes have been observed to acquire resistance, they have also been found to lose this drug-fastness after cyclical passage through different hosts. Werbitzki and Gonder (1911) found that an arsenophenylglycine-fast strain of *T. lewisi* lost the resisting character after passage through the rat louse. Morgenroth and Rosenthal (1911) observed gradual loss of resistance to arsenic in certain strains. Mesnil and Blanchard (1916) noted that passage through mice lessened the resistance of trypanosomes to human serum. Voegtlin and his co-workers (1924) reported that arsenic resistance can be reduced temporarily by passing a given strain through another mammalian host, such as rabbits and dogs. Yorke, however, by passing the resistant strains of *T. brucei* through the tsetse fly found that they preserved the resistant character unimpaired.

Whatever may be the specific character of drug-fastness in trypanosomiasis, the available evidence justifies the conclusion that it can be produced experimentally. But whether strains of resistant parasites develop in man during a course of treatment, it is difficult to say. There is no satisfactory evidence demonstrating the existence of these drug-proof trypanosomes in man. It has, however, been observed that drug resistance is

correlated with the chemical nature of the aromatic arsenicals. The pentavalent compounds of arsenic do not produce, as a rule, drug-fastness in trypanosomes to the same extent as do the trivalent compounds. A drug-resistant strain is more easily developed with arsphenamin than with neoarsphenamin. The chance of development of resistance is, moreover, dependent on the dosage, the quantity of drug administered and the timing of such treatment. If the doses are just below the quantity which will effect a cure, then repetition of such subcurative doses will help to produce a strain of drug-resistant trypanosomes. In this way, a strain can withstand several hundred times the dosage lethal to the normal parasites. In man such an occurrence may actually happen.

Drug-resistance in spirochaetosis. The existence of drug-resistant groups of spirochaetes is a matter about which little is known. After intermittent treatment with gradually increasing sublethal doses of arsenicals, spirochaetes are known to acquire resistance to the drug.

Margulies (1910) treated hens infected with *Treponema anserinum* with subeffective doses of salvarsan and after forty-six passages succeeded in producing in them a strain of these organisms, which could withstand double the original curative dose. Rothermundt and Dale (1911) could not, however, produce a resistant strain of *T. anserinum*. Gonder (1912), working with a Russian strain of *T. recurrentis* in mice, succeeded in producing a strain much more resistant than the original. Kritchewski (1927), in working with different strains of spirochaetes of relapsing fever in mice, found that certain strains could be sterilised with a maximum dose of salvarsan, while others proved very resistant. Akatsu and Noguchi (1917) were successful in increasing the tolerance of *T. microdentium* and *T. refringens* to increasing doses of various chemotherapeutic agents, such as salvarsan, neosalvarsan, bichloride of mercury, and iodine-potassium iodide solution (Lugol's solution) *in vitro*. Fe'dt (1932) produced a strain of *T. recurrentis* in mice, which could, after successive passages in the animal, withstand five times the original lethal dose. Likewise, the existence of solganol-fast strains is also recorded. There have been cases of failure with novarsenobillon in human relapsing fever recorded by several observers, though the drug has been recognised as a specific for the disease. There is thus evidence that such a thing as drug-resistant spirochaetes may occur.

In syphilis. It has been observed that certain cases of syphilis do not respond to mercury and iodide preparations. In

many countries the impression has been gaining ground that the results of treatment of syphilis with arsphenamin and similar preparations are not giving such promising results as in pre-War days. Silbersterin (1924) stated that it is becoming increasingly difficult to produce a negative Wassermann reaction in patients, though Moore and Robinson (1930) doubt the statement and attribute it more to the reaction of the individual to treatment than to the occurrence of arspenamine-fast strains of *T. pallidum*. The general trend of opinion in the treatment of syphilis is that the antisyphilitic remedies, such as salvarsan and neosalvarsan, have to be used in gradually increasing doses in order to obtain the maximum, parasito-tropic effect of the drug without the organotropic effect. If repeated subeffective doses are given, the chances of eradication of spirochaetes are less. This raises the question of arsenic resistance of the parasites, to avoid which Ehrlich advocated his doctrine of *therapia sterilisans magna*, but the latter is beset with practical difficulties.

The results of experimental work on this drug-fastness of Treponema to arsenic and various compounds are not at all confirmatory. Mergulies (1910) was unsuccessful in producing an arsenobenzene-fast strain of rabbit syphilis. Nichols (1911) in working with rabbit syphilis could not find any arsenic-fast properties in them after 4 exposures. In his series one relapse occurred, which is explained as being due to the drug not being able to reach the spirochaetes hidden in the tissues away from the site of action of the drug. Akatsu and Noguchi (1917) showed that *T. pallidum* increased its tolerance to salvarsan and neosalvarsan, in 3 to 4 months, to five and one-half times its original mark; against the action of bichloride of mercury the amount of increased tolerance was about 35-70 times the original and that the increased drug-fastness had a certain limit, beyond which no further advance could be made. Klauder (1924) could produce a strain of *T. pallidum*, whose resistance to arsenic was increased to a maximum of 68 per cent. with nine injections of ascending doses of arsphenamin, and after six transfers of the infection from one animal to the other.

In view of the aforesaid clinical and experimental data, it does not seem improbable that *T. pallidum* may acquire a certain degree of resistance to the action of arsenical compounds.

Drug-resistance in amœbic dysentery. With regard to amœbic dysentery there has been a strong belief that emetine-fast amœbæ occur. Experimentally, strains of *Entamœba histolytica* have been produced, which are fast to emetine and acriflavine. The inability to rid the patient of amœbæ even after maximum doses of emetine hydrochloride has been recognised by many clinicians in the treatment of chronic amœbic dysentery. To what this failure may be attributed, it is difficult to state at present. The transformation of the vegetative parasites to the cystic forms, alteration in the tissues of the host affording a chance for the parasites to ward off the action of a chemical, the peculiar character of drug-fastness of the strain, all or some of these, may contribute to the results. It has, however, been observed that cases resistant to emetine react normally to carbarsone, yatren or to other non-alkaloidal amœbicidal remedies.

Quinine-resistance in malaria. Similarly, resistant cases of malaria have been described by several workers. Inability to prevent relapse in many cases of plasmodium infection has been ascribed by many as due to the resistance of the parasites to quinine. James (1913), who investigated fully the subject of relapse, states that the failure of quinine therapy may be due to one of the following factors: (i) infection with different species of parasites, (ii) non-absorption of quinine from the gastro-intestinal tract, (iii) neglect to take the full dose, (iv) drug-resistance of the parasites. MacGilchrist (1915) could not, however, find any instance of quinine-resistance among his patients in India. Acton and others (1920) stated that a relapse for the fifth time could be equally controlled with quinine, with disappearance of the parasites from the peripheral blood.

The different strains of malarial parasites occurring in different parts of the world behave differently to quinine; the difference between endemic and epidemic malaria is widely recognised. James (1927), in a tentative trial of malaria therapy, used different strains of malarial parasites. It was found that the cases infected with Rome or Sardina strains were more severe than those infected with the Indian strains. The dose required

to control a primary attack of malaria caused by the former strains was about eight times greater than the dose required to control an attack caused by the latter. Also the effect of quinine was less marked in cases where the primary attacks were caused by the bites of many mosquitoes than when they were caused by the bites of one or two mosquitoes.

Whether quinine fails to rid the blood of malarial parasites owing to the acquisition of the property of drug-fastness on the part of the parasites or to some other causes, is not definitely known. Fletcher mentions a case of possible quinine-resistant malaria in a Tamil woman. Et. and Ed. Sargent (1921), in investigation on bird malaria, observed resistance to quinine in one of them and the parasites retained their resistant character even after passage through two other canaries.

Though quinine-resistant parasites may occur, the possibility of the development of this character in practical therapeutics seems to be small. Evidence available does not at present warrant the view that the failure of quinine treatment in some cases is due to the occurrence of quinine-resistant parasites. The mode and virulence of infection, the degree of susceptibility of the individual, the species and the geographical race of the parasites, are also to be taken into consideration in the alleged cases of failure with quinine. Faulty methods of administration and inadequate dosage may be responsible for many of the cases of failure. In addition, non-absorption of the alkaloid from the gastro-intestinal tract has also to be considered, before the existence of quinine-resistant parasites can be proved.

THE RETICULO-ENDOTHELIAL SYSTEM

Introduction. In recent years the reticulo-endothelial system has attracted a great deal of attention from workers interested in different branches of medical science. The anatomist, the physiologist, the pathologist, the hæmatologist and the immunologist have all evinced great interest in the study of this system and in the solution of one or more of its innumerable problems. The pharmacologist, who is interested in

obtaining a knowledge of the mechanism of action of drugs, has also been directing his attention to this system in the hope that a study of it might be helpful in furnishing answers to some of his problems. A perusal of the literature on the subject reveals that the efficacy of many drugs, including some of the so-called specific ones, may depend upon the functional efficiency of this system. The earlier view expressed by Ehrlich and others that the chemotherapeutic action of drugs depended entirely on their direct action on the causative agent of disease, has now few supporters. The accumulating evidence appears to be distinctly in favour of the view that drugs, in the majority of instances, act in an indirect way through the tissues of the body, and particularly through the cells of the reticulo-endothelial system. Time and further work alone can determine the exact role of this system in infection, immunity and chemotherapy. Incomplete though the knowledge may be at the present time, there seems to be very little doubt that the reticulo-endothelial system plays a part of great importance in recovery from diseases, more specially from those like typhoid fever, tuberculosis, spirochaetal infections, malaria, kala-azar and trypanosomiasis. In view of its increasing importance in tropical diseases, it seems necessary to give a brief description of the system, its accepted functions in health, and the part it plays in the cure of disease.

Definition. Widely scattered in the blood and tissues of man and other vertebrates, there are certain cells of mesenchymal origin and of the macrophage or large mono-nuclear type that possess the primitive capacity for phagocytosis and intracellular digestion. These take up all foreign particles that gain access to the body, whether they be inert or colloidal, inanimate or animate, bacterial or protozoal, and dispose of them in a manner best suited to the body economy. They collectively go by the name of the "reticulo-endothelial system."

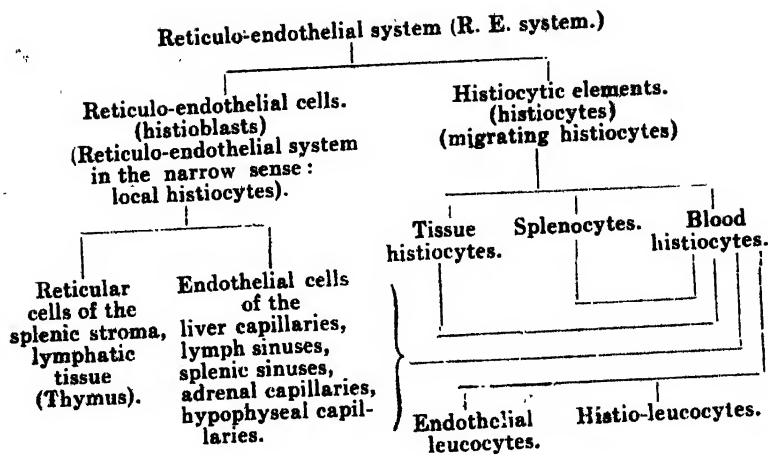

Evolution. The evolution of the reticulo-endothelial system is closely associated with the origin and development of parasitism and host-parasite adjustments. "In the long course of evolution of living things, it seems probable that the lower forms of life arose far in advance of the more highly differentiated forms. From the very moment of

their first appearance upon this earth the latter had to compete for their place in nature with a vast number of microbial forms. In the course of the adjustments necessitated by this complex communal existence, various forms of parasitism were established. In many instances invasion of a host by a parasite was fraught with danger, and as a defence against it, mechanisms of protection of different degrees of efficiency were developed. Even in the most primitive forms of life one or more simple means of self-defence are discernable; as the needs for self-preservation become greater the mechanism of defence also becomes more complex." (W. W. C. Topley). In the unicellular animal the function of protection is performed by the cell itself and is merely an adaptation of the ordinary feeding mechanism. In lowly organised metazoa this function is relegated to certain special cells. In higher vertebrates and in man these cells of protection are very highly differentiated and are distributed widely throughout the body, and go by the name of the reticulo-endothelial system.

Historical. The history of the recognition of the cells of the reticulo-endothelial system may be said to have begun about the end of the nineteenth century. Mallory's 'endothelial leucocytes' and Metschnikoff's 'macrophage cells' are now recognised to be reticulo-endothelial cells and these workers, therefore, may well claim to be the first to recognise and point out the importance of these cells. Several subsequent workers also met with these cells under various circumstances and referred to them under different names. In 1913, Aschoff and Landau proposed to group together these differently named cells into a single system and to call it 'the reticulo-endothelial system.' In 1924, Aschoff gave a detailed description of the anatomical distribution of the cells composing the system and pointed out their functional unity and stressed their immunological importance.

Distribution. The reticulo-endothelial cells have a very wide and scattered distribution throughout the body. They are to be found in organs, such as the spleen, liver, lymphoid tissue, bone-marrow, connective tissue, blood and endocrine glands. Amongst these organs, the spleen may be considered the largest store-house of these cells. The amount stored in the spleen as compared with other organs varies not only in different species of animals but also in different members of the same species. It has been found that after the removal of the spleen, regeneration of the reticulo-endothelial cells takes place more quickly and markedly in certain species of animals than in others. This has led to the presumption that the amount of reticulo-endothelial cells outside the spleen is also very variable and dependent upon the animal species. For the sake of clearness, the anatomical distribution of the cells of the reticulo-endothelial system as classified by Aschoff is given below in a tabular form.

CHEMOTHERAPY

Composition. Originally, Aschoff (1924) classified the cell elements of the reticulo-endothelial system into six groups according to the intensity of vital-staining and the size and compactness of the dye granules present in their cytoplasm. These groups are:—

- (a) The *endothelial cells* of the blood and lymph vessels.
- (b) The *fibrocytes* or ordinary connective tissue cells.
- (c) The *reticulum cells* of the splenic pulp and lymphoid tissue.
- (d) The blood *monocytes* and *splenocytes* [related to group (e) and (f).]
- (e) The *reticulo-endothelial cells* lining the sinuses of the spleen, bone marrow, adrenal cortex and hypophysis.
- (f) The *histiocytes* or the large phagocytic motile cells of the connective tissue.

Of these six types, the first and the second are the least phagocytic, the third and the fourth moderately phagocytic, and the fifth and sixth the most phagocytic.

The cells of the reticulo-endothelial system have been classified by Sabin into two main groups, namely, 'monocytes' and 'clasmatocytes.' The term 'histiocytes' is preferable to 'clasmatocytes.' Under normal conditions these two types of cells are found in all organs containing reticulo-endothelial cells. The ratio of monocytes to histiocytes in spleen puncture material is generally 6 to 1. In the peripheral blood, histiocytes are normally absent and the only representative of the reticulo-endothelial system is the monocyte. In pathological states and after experimental stimulation, histiocytes as well as all grades of intermediate forms have been found in the peripheral blood. These intermediate forms probably

represent stimulated monocytes with increased phagocytic power. The reticulo-endothelial system has come to be recognised now as composed of two closely allied cell types. These cells differ in morphology and possibly in function. The histiocytes are said to play the chief rôle in the phagocytic mechanism of defence, while the monocytes are more closely associated with antibody production.

Morphology. Normally, the two chief cell types composing the reticulo-endothelial system, as seen in supra-vital preparations, are quite distinct morphologically and can readily be distinguished from one another. Typical specimens of the two types may be seen in the blood of malarial cases twenty-four hours after an injection of quinine, or in the spleen juice of an advanced case of kala-azar prior to treatment. In these experimental and pathological conditions, some difficulty may be felt in classifying some of the forms intermediate between monocytes and histiocytes. With a little experience and discretion, this difficulty can easily be overcome. The following are some of the characteristics of the two cell types, in supra-vital preparations.

Monocyte. This cell is slightly larger than the lymphocyte, which it closely resembles. It has a big kidney-shaped nucleus with a deep and distinct indentation or 'hof' and shows the presence of a 'rosette' or clump of uniformly fine, neutral red particles at the 'hof' and a number of blue-staining mitochondria in its cytoplasm. Occasionally, a few small neutral red vacuoles may be seen in addition at the periphery of the cell. The chief characteristic for purposes of identification is the peculiar segregation of neutral red in the form of a 'rosette' of fine granules at the 'hof' of the nucleus. Even when the cell is stimulated and is showing increased phagocytic activity, this 'rosette' formation is noticeable; the only difference is that the 'rosette,' as well as the individual granules composing it, are very much bigger in the stimulated cell than in the normal cell. The presence of mitochondria helps to distinguish the cell from the histiocyte in which they are generally absent.

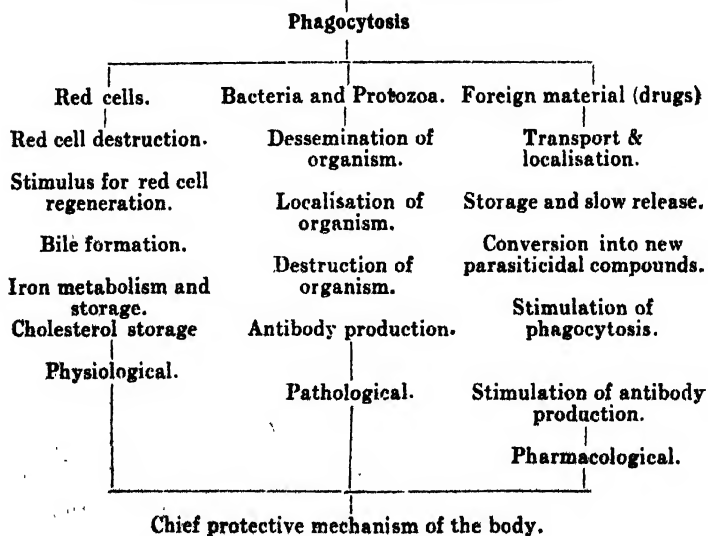

Histiocyte. This is a much larger cell than the monocyte; its nucleus is very variable in shape and differs from that of the monocyte by being small in comparison to the size of the cell, by being often oval rather than kidney-shaped and by occupying a more or less central rather than an eccentric position. The protoplasm of the histiocyte is somewhat granular, and mitochondria are generally absent, although occasionally, a cell may be seen with a few of them. The chief characteristic by which the cell is identified, is the way in which it segregates neutral red. Being very much more phagocytic than the monocyte, it takes up a larger amount of the vital dye and instead of segregating the dye in one place as the monocyte does, it distributes the dye diffusely in the form of large vacuoles in its cytoplasm. Another distinguishing feature noticeable, sometimes, is the presence of red blood corpuscles,

cell debris, platelets, within the cytoplasm. These are not always present, but when they are there, identification of the cell is much easier.

Functions of the Reticulo-Endothelial System

The reticulo-endothelial system performs a multiplicity of important functions both in health and in disease. We already stated that phagocytosis is the chief characteristic of the cells of this system and to it we may add that it is this property that helps it to perform almost all its functions. The best way to understand how that is done will be by tracing the sequence of events as they take place after phagocytosis of different materials. The substances that these cells are known to ingest may be divided broadly into three main groups, namely (a) red cells, (b) organisms, such as bacteria and protozoa, and (c) foreign materials, such as drugs. For the sake of clearness the results of phagocytosis of these substances have been classified in a tabular form and then discussed separately in detail.

Functions of the Reticulo-Endothelial System

Phagocytosis of Red Cells

Red cell destruction. It is an accepted fact that the cells of the reticulo-endothelial system take up for purposes of destruction those red cells whose allotted span of life is over and also those that get damaged by inflammatory processes, toxins or parasites. In such diseases

as malaria, kala-azar, typhoid fever, Weil's disease and poisoning by arseniuretted hydrogen in birds and phenyl hydrazine in dogs, phagocytosis of the damaged red cells can easily be observed. When hæmoglobin is injected into the circulation it is also taken up by these cells. *In vitro*, in tissue culture, the histiocytes have been observed to ingest red cells. Thus all observations made so far go to show that the histiocytes pick up old, damaged or dead red cells in order to destroy them. There appears to be no evidence, however, to suggest that they phagocytose healthy and young red cells.

Red cell regeneration. Under normal conditions red cell destruction and regeneration are in a state of equilibrium and this helps to maintain the red cell count at a constant level. The organ that is chiefly responsible for the control of the equilibrium appears to be the reticulo-endothelial system. The stimulus for red cell production is furnished by the histiocytic elements after they have ingested and digested the red cells. It has been shown that when there is functional failure of histiocytes, blood destruction is not followed by regeneration to any appreciable extent. It is, therefore, probable that the reticulo-endothelial system provides the stimulus for regeneration of red cells and that in the absence of such stimulus the bone marrow fails to produce a sufficient number of red cells to make up the loss sustained.

Bile pigment formation. The old view that hæmoglobin from destroyed red cells is brought to the liver and there gets converted by the glandular cells of that organ into bilirubin, is now recognised to be erroneous. McNee (1913), following upon Aschoff's description of the reticulo-endothelial system and as a result of some of his own experimental observations, suggested that the reticulo-endothelial system as a whole is responsible for bile formation. Subsequent workers clearly established, by extirpation of the liver and other experiments, that bile pigment is formed in all tissues in which reticulo-endothelial cells are present, including Kupffer's cells in the liver, but not by the glandular cells of that organ. Further confirmatory proof was obtained by the demonstration of bilirubin crystals within histiocytes after they had phagocytosed and destroyed the red cells. Therefore, all are agreed that one of the important functions of the reticulo-endothelial system is the elaboration of bilirubin.

Iron metabolism. One of the products of digestion of red cells and hæmoglobin is iron. There is increasing evidence to show that the reticulo-endothelial system is concerned in the metabolism and storage of this metal. In certain diseased states, such as pernicious anæmia, inanition of infants, toxic hæmolytic jaundice, malaria and after repeated injections of hæmoglobin, deposits of iron may be found in some of the cells of the reticulo-endothelial system. After splenectomy and experimental blockade of this system a marked disturbance of iron metabolism is often noticeable. It is highly probable, therefore,

that the system is of importance in the storage and metabolism of this metal.

Cholesterol metabolism. Storage of cholesterol appears to be another function of this system. Whenever there occurs an excess of cholesterol in the blood, either as a result of experimental cholesterol feeding or in certain diseases, such as diabetes, lipæmia, some cases of icterus and contracted kidney, the excess of cholesterol is taken up by the histiocytic elements of the liver, spleen and skin, and may be seen infiltrating these cells. The peculiar skin tumours at times seen in diabetics, (*Xanthoma diabeticorum*) are nothing but collections of histiocytes loaded with cholesterol esters and allied substances. These findings leave no doubt as regards the role of the system in cholesterol and lipid metabolisms.

Phagocytosis of Parasitic Organisms

Bacteria. As long ago as 1886 Wyssokowitsch showed that bacteria injected intravenously are taken up largely by the endothelial cells of the spleen. Werigo in 1894 injected anthrax bacilli into dogs and found the organism deposited in certain cells of the spleen, liver and lungs. Bull (1914-16) injected intravenously into rabbits and dogs living pneumococci and typhoid bacilli and demonstrated their presence shortly afterwards in organs rich in reticulo-endothelial cells, such as the spleen and liver. Wright, using virulent and non-virulent pneumococci, showed that within a few minutes of their introduction into the circulating blood, they were engulfed by the cells of the reticulo-endothelial system and conveyed to the internal organs. Durham, Buxton and Torrey (1906), Berry and Melick—all showed that bacteria injected into the peritoneal cavity were similarly engulfed by the cells of the reticulo-endothelial system and carried to internal organs, such as the liver and spleen, for purposes of destruction. The same phenomena were also observed after subcutaneous injection of living organisms. Although in the case of injections of pyogenic cocci the polymorphonuclear leucocytes phagocytose the organisms in larger numbers, evidence is not wanting that the reticulo-endothelial cells also play an important part in their removal. In addition to the above experimental evidence there is also proof of phagocytosis of organisms in many infectious diseases. Everyone is familiar with the presence of different bacterial organisms within macrophage cells in films of inflammatory exudates. In infectious diseases like pneumonia, typhoid fever, bacillary dysentery, tuberculosis, leprosy, actinomycosis and spirochætal diseases, the reticulo-endothelial cells may actually be seen loaded with these organisms in infected tissues. In all these diseases and in the granulomatous diseases, in particular, the characteristic cellular reaction is a proliferation and multiplication of the reticulo-endothelial cells, and the tubercle, the leproma and the gumma, are all formed as a result of this specific cellular

immunity reaction. The above evidence is convincing enough to prove that the reticulo-endothelial cells do phagocytose living bacteria that gain access to our bodies.

Protozoa. There is considerable evidence to show that the blood-inhabiting protozoa are also phagocytosed by the cells of the reticulo-endothelial system. As far back as 1898 MacCallum actually observed macrophage cells taking up malarial parasites in birds. All subsequent workers have corroborated this finding and have repeatedly found red cells and malarial parasites within the large mononuclear cells. Despite this, there are some who still believe that the cells of the reticulo-endothelial system take up only dead or dying malarial parasites. Recent observations in connection with the role of the reticulo-endothelial system in malaria have shown that the cells of the reticulo-endothelial system phagocytose living as well as dead malarial parasites (Krishnan, Napier and Lal, 1933). In kala-azar, oriental sore and dermal leishmaniasis *Leishmania donovani* are only found within the cells of the reticulo-endothelial system. Experimentally, when *L. donovani* are injected into susceptible animals, irrespective of their route of entry, subcutaneous, percutaneous, intravenous, intrapleural or intraperitoneal, they are picked up by the cells of the reticulo-endothelial system and carried to the spleen, liver and bone marrow. There they live and multiply within these cells. In Hepatozoon infections in cats, rats and squirrels, schizogony occurs in the mononuclear cells of the spleen and bone marrow and gametocytes are found in the circulating mononuclear cells. In trypanosome infections, although phagocytosis of the parasites has been observed, it does not appear to be a very pronounced feature. As regards phagocytosis of other protozoa by the reticulo-endothelial cells there is very little evidence. Taking the available data into consideration, we may say that the cells of the reticulo-endothelial system are capable of phagocytosing many of the blood-inhabiting protozoa.

Helminths. There is no evidence that the cells of the reticulo-endothelial system phagocytose helminthic worms that gain access to the blood or tissue. It is probable that they take up antigenic substances liberated from the worms, either during their life or after their death and disintegration, and lead to the production of antibody. What part this antibody plays in overcoming the helminthic infection it is not possible to say and as such the role of the reticulo-endothelial system in diseases due to worms still remains a mystery.

Fate of ingested organisms. Having shown that phagocytosis of bacteria and protozoa by reticulo-endothelial cells does occur, we may consider next the fate of the ingested organisms. Are they destroyed within the cells or do they live and multiply there? Both in the case of bacteria and protozoa, phagocytosis is not always followed by death of the ingested organisms. While it is true that large numbers of

them are killed by these cells, there is enough evidence to show that some of the organisms survive and even multiply within these cells. In the case of leishmania and hepatozoon infections, the parasites actually live and multiply within the reticulo-endothelial cells. Rous and Jones (1916) showed that certain bacterial organisms are found alive within phagocytes, and that the latter at times afford the bacteria protection from the injurious effects of serum antibodies in their environment. Bull (1916) showed that phagocytosis of pneumococci by reticulo-endothelial cells of partially-immune dogs resulted in the dissemination of the infection and the production of complications, such as meningitis and death of the animals. From the above evidence it is clear that phagocytosis and destruction are two separate functions of the cell and need not necessarily be present together at one and the same time. Depending upon the functional state of the cell, the nature of the organism ingested, and certain other factors, death may or may not occur after phagocytosis. It has been shown that one of the factors that helps to destroy parasites effectively is specific antibody. Although the importance and value of antibodies in different infectious diseases vary, being probably high in virus and certain bacterial infections, moderate in protozoal infections, and slight in helminthic infections, there is evidence that antibodies do sensitise all parasites in such a way that other destructive processes, such as phagocytosis and lysis, can carry on their functions more successfully. As antibodies are supposed to be a product of the reticulo-endothelial system, consideration of the views regarding their formation will be of interest.

Antibody production. The site of formation of antibody has been a disputed question for a considerable time. Years ago Metchnikoff suggested that the macrophages secrete some kind of ferment which help them to destroy the parasites that they ingest. Later, this view was given up, and the belief arose that antibody was elaborated by all tissues locally, at the site of inoculation of antigen. Recently, a large number of investigators studied this question and their work strongly indicates that formation of antibody takes place only in the reticulo-endothelial system. The splenectomy experiments of Hektoen and Curtis and the blockade experiments of Reiling and Isaac, Gay and Clark, Jungeblut and Berlot, are all in favour of this view. The most suggestive evidence, however, in this connection has been obtained by tissue culture work. Carrel and Ingebrigstson (1912) detected the presence of hæmopsonins and hæmolysins after the addition of goat's red cells to tissue culture of bone marrow and lymph glands from guinea pigs. Ludke (1912) confirmed their findings using ox and sheep corpuscles and showed, in addition, that agglutinins and lysins for typhoid and dysentery organisms could be obtained in a similar manner. More recently, Schiff (1928), Meyer and Löwenthal (1928), obtained bacteriolysins for cholera vibrios and typhoid bacilli by tissue culture methods.

From these and other data it is evident that an antigenic substance irrespective of its source or nature introduced into the animal tissue is taken up by the cells of the reticulo-endothelial system and removed to organs, such as the spleen and liver, where they stimulate the production of suitable antibody. Antibacterial, antitoxic and lytic antibody are all formed according to requirements.

Phagocytosis of foreign material. The chief characteristic of the reticulo-endothelial system that led to its discovery is phagocytosis of foreign substances. There is an enormous amount of evidence to show that its cells readily ingest substances like vital dyes, carbon, and Indian ink particles. If, for instance, one of these substances is injected intravenously into a rabbit and then films from spleen, liver and lung are examined, particles of the injected substances can be detected within the reticulo-endothelial cells. While very little difficulty is experienced in demonstrating the presence of inert and coloured particles, such as those mentioned above, the detection of soluble chemical substances (drugs) that are generally used in the treatment of disease, is a difficult matter. By the use of microchemical tests and special staining methods, colloidal and organic preparations of metals, such as iron, silver, antimony, bismuth and arsenic, have been shown to be present within the reticulo-endothelial cells. As regards the finding of alkaloidal and other drugs, *e.g.*, quinine within these cells, there is very little evidence; it is possible that they are also taken up by these cells and removed to the spleen, bone marrow, suprarenals and kidney. Until more work on these lines is performed it will not be possible to say which substances the reticulo-endothelial cells do and which they do not take up.

Regarding the disposal of particular substances after phagocytosis, there is evidence that the reticulo-endothelial cells in the course of their wandering, transport them to various organs and tissues (lung, liver, spleen, bone marrow and kidney), where they are either eliminated or stored. As regards the fate of soluble chemical substances very little is known; probably a considerable quantity is excreted within a short time through the normal channels of elimination and only a very small quantity is found in the body, possibly in the reticulo-endothelial cells. Here they are present either in their original state or in an altered form. As most of these foreign substances gain access to the body as drugs, at a time when it is in a diseased state, the question of prime importance is how they bring about cure and beneficial results and what part the reticulo-endothelial system plays in it. This brings us on to a consideration of the rôle of the system in chemotherapy.

Reticulo-Endothelial System in Chemotherapy

It is unfortunate that despite a large amount of experimental work very little progress has been made in the understanding of the mode of action of drugs in diseased states or of the role of the reticulo-endothelial system in pharmacotherapy. The reasons for this unsatisfactory state of affairs are not difficult to understand. In the case of virus and bacterial infections no drug has so far been discovered that can be called a specific, and in most instances the causative organism cannot easily be detected by direct examination of the blood or tissues. In the case of protozoal infections we, however, possess a knowledge about the specific action of some drugs. In addition, also the effect of these drugs upon the parasites can easily be studied. Being of far bigger size than bacteria and more easily demonstrable in the blood and tissues by direct examination of smears we can get a true picture of the effect of treatment on protozoa and on the course of infection, and we can also correlate these findings with various cytological and serological changes. This has enabled workers to tackle several of the problems in chemotherapy through investigations on protozoal infections, such as malaria, kala-azar and trypanosomiasis. A perusal of the studies conducted on these lines at the School of Tropical Medicine will show that very interesting and instructive results have been obtained. As regards helminthic infections the hindrances to progress have also been many and our knowledge of the mode of action of anthelmintic drugs is at present not very satisfactory. Nevertheless, taking the evidence as a whole, there appears to be very little doubt that chemotherapeutic action of drugs in general is not merely a simple direct action on the parasites. It may be true that in certain helminthic diseases, and possibly also in some protozoal infections, the action of specific drugs is predominantly a direct one, but with regard to the majority of other remedies, there is absolutely no evidence that they have any marked parasitocidal effect. It has repeatedly been shown that parasites are actually more vulnerable to drugs when they are brought into contact with them

within the body than outside it. Furthermore, drugs are rapidly excreted from the body and the dilution in which they occur in the blood and tissues after their administration in therapeutic doses is so very high that simple direct action alone can hardly be said to account for their efficiency. Blockade and splenectomy experiments have clearly established that dysfunction of the reticulo-endothelial system reduces and at times completely abolishes the therapeutic value of drugs. In view of these and other observations the consensus of opinion is that the reticulo-endothelial system plays an important part in chemotherapy. It would appear that in bringing about cure, the direct action of drugs on parasites is of the greatest importance in helminthic infestations, of moderate importance in protozoal infections, and of the least importance in virus and bacterial infections. As regards the importance of the reticulo-endothelial system in overcoming infections, the reverse order appears to be the most likely, *i.e.*, the system plays a part of slight importance in helminthic diseases, of moderate importance in protozoal diseases, and of the highest importance in bacterial and virus diseases. How far this view is correct time alone can decide.

Mode of action. When we take up for consideration the different ways in which the reticulo-endothelial system can possibly help drugs in bringing about a cure, four methods suggest themselves.

(1) That it acts as a store-house for the drug and releases it slowly as required—thereby preventing rapid elimination and ensuring continuous supply.

(2) That it carries the drug to the neighbourhood of lesions, where it is most needed.

(3) That it elaborates new compounds from the drug with greater parasitocidal power.

(4) That it is stimulated by the presence of the drug in circulation and thereby its functions of phagocytosis and antibody production become more pronounced and effective.

In support of the above view, we may cite the following evidence. Kritschtski (1928) showed that when germanin was

injected in a basis of 6 per cent. agar, its efficiency was greater on account of the slow rate of absorption of the drug from the agar which acted as a 'second spleen.' This supports the first contention.

Boyd, Napier and Roy (1931) showed that after injections of antimony compounds into monkeys, the highest concentration of the drug was found in the liver, where there was also a concentration of infection with *Leishmania*. It has also been experimentally shown that the reticulo-endothelial cells localise certain colloidal substances, especially those that carry a negative electric charge in inflamed tissue in preference to other tissues (Burrows, 1932). This clearly establishes the second contention.

Jiminez de Asua, Kuhn and Torino (1928), from a study of the action of arsenic compounds in splenectomised and non-splenectomised animals, have produced evidence to suggest that the reticulo-endothelial system is probably concerned in the conversion of these compounds into more efficient germicidal substances. The work of Jungeblut (1927) and Kristschewski (1927) support this work and all of them corroborate the third contention.

Krishnan (1933) has shown that the phagocytic function of the cells of the reticulo-endothelial system is stimulated by quinine in malaria and that this is partly responsible for the cure of the disease. It has also been shown by this worker that antibody formation is increased after antimony treatment of kala-azar and that this probably is responsible for cure. These observations lend support to the fourth contention.

Further evidence in support of the above can be obtained from a discussion of the mode of action of some of the important drugs used in the treatment of different infectious diseases. The following is a brief reference to some of them :—

Helminthic infections. The role of the reticulo-endothelial system in the chemotherapy of anthelmintic drugs is not fully understood. Although the evidence is strongly in favour of the mode of action of these drugs being a direct one on the worms themselves, there are suggestions in certain cases, that the beneficial results obtained may be attributable, in part at least, to an indirect action, which is dependent upon

the functional efficiency of the reticulo-endothelial system. This view appears to be supported, partly at least, by the results of treatment of helminthic infections of the blood and tissues. The actions of tartar emetic and emetine in the treatment of schistosomiasis, of atoxyl and antimony in filariasis, of gentian violet in clonorchiasis, and of trypanamide in chyluria are in all probability indirect, through the reticulo-endothelial system. The dermal tests reported to be useful in the diagnosis of some helminthic infections, such as schistosomiasis, hydatid disease, trichiuriasis, filariasis and intestinal worms, are evidence of sensitisation to antigenic substances from the worms, and are most likely due to sessile antibodies elaborated by the reticulo-endothelial system. If it is so, then the system may be presumed to play some part in the cure of these infections. But at present we are not in a position to understand what exactly is the role of these antibodies in helminthic diseases. Further work on the subject can alone elucidate this point.

Protozoal infections. The role of the reticulo-endothelial system in the treatment of protozoal infections has been extensively studied. Although there are several drugs which may be called specifics and which are known to act indirectly through the reticulo-endothelial system, the mode of action of a few of the more important ones alone is discussed below.

Emetine. While there is evidence to show that the therapeutic efficiency of this drug in human amoebiasis is probably due to a direct action of the alkaloid upon *E. histolytica*, the work of Dale and Dobell clearly suggests "that emetine and the amoeba are not the only factors to be considered in the cure of dysentery and that the missing factor is probably the interaction between emetine and the host's tissues." If this is correct, then what other tissue of the host can play this important part more successfully than the ubiquitous reticulo-endothelial system? The available evidence does not suggest the way in which the system enhances or ensures the efficiency of the drug.

Quinine. The mode of action of quinine in malaria has been studied by different workers, and yet the views regarding

it are still very varied. While some believe that the drug attacks the parasites directly, others claim that it acts in an indirect manner through the host's tissues. Yorke and Macfie favour the view that antibodies play an important part in cure, while Taliaferro and Cannon (1931), Krishnan (1933) and others have obtained evidence that phagocytosis by cells of the reticulo-endothelial system is the chief factor in overcoming malarial infection. Recently, the large series of experiments carried out at the School of Tropical Medicine, Calcutta, have furnished strong evidence regarding the important part played by the reticulo-endothelial system in the cure of malaria. It has been shown that quinine, by accelerating the natural processes of mobilisation, proliferation and functional activation of phagocytic large mononuclear cells, brings about rapid engulfment and ultimate destruction of the malarial parasites. Whenever the drug fails to elicit the suitable reticulo-endothelial response, no improvement is noticeable, and after splenectomy of monkeys infected with *P. knowlesi* quinine fails to bring about the same degree of beneficial results as when the organ is present. These results leave no doubt that the reticulo-endothelial system plays a part of greatest importance in the cure of malaria by quinine. By this we do not mean that the direct action of the drug on parasites and infected red cells is of no consequence, for it has been shown that when the direct action is pronounced, it is very helpful in enhancing the phagocytic and destructive powers of the reticulo-endothelial system.

Antimony. The mechanism by which antimony destroys *Leishmania donovani* and brings about cure of kala-azar is still unknown. It is very doubtful that it is a direct parasitocidal action. Noguchi (1924) showed that tartar emetic has no action on *Leishmania donovani* cultures *in vitro*, and certain unpublished results of Napier and Haldar also show that *Leishmania donovani* grows as luxuriantly in N. N. N. tubes, to which neostibosan and aminostiburea are added, as in control N. N. N. tubes. When antimony compounds are injected intravenously, they are excreted rapidly in the urine (30 to 40 per cent. within 24 hours, and over

80 per cent. within 72 hours); the dilution in which antimony is present during the short period of its stay in the circulation, is very high, and no direct action on the parasites can possibly be conceived of, in such low dilutions. The opinion that its action is through the tissues of the body is, therefore, fast gaining strength. Brahmachari (1928) suggested that probably urea stibamine is converted into a trivalent oxide of antimony by the host's tissues in a manner similar to what happens in the case of compounds of arsenic and that this oxide is more parasitotropic. It is no doubt true that some of the antimony injected is taken up by the cells of the reticulo-endothelial system, but there is no certain evidence either of its conversion into stiboxyl or of the latter's higher parasitocidal properties. In experimental kala-azar in animals, such as mice and hamsters, it has been repeatedly shown that antimony fails to bring about cure of their infection. The 'clasmatocytes' that are supposed to effect the transformation of the drug to stiboxyl are present in them, and there is also evidence that these cells take up the injected antimony. Why then do they not convert the drug into the oxide and bring about the death of the leishmania parasites in them? Acton and Chopra (1927), and Chopra and Das Gupta (1929), found that when antimony compounds are injected intravenously into kala-azar patients, it causes enlargement and rhythmic contractions of the liver and spleen and that this is due to an increased functional activity of the adrenals. This observation led them to suggest that the alteration in the permeability of the vascular walls brought about by the hyper-activity of the adrenals caused a diminution in the permeability of the cells of the reticulo-endothelial system and this in turn led to the starvation and death of the leishmania parasites present in them. Krishnan (1930) confirmed these findings in an indirect manner by studying the changes in the leucocyte picture after adrenalin injection into kala-azar cases, before, during, and after, treatment. This work clearly indicated that a condition of hypoadrenia existed in kala-azar cases and that treatment helped to bring about a normal condition. But what part this alteration in the adrenalin

content played in overcoming the infection could not be clearly determined. In continuation of this work Napier, Krishnan and Lal (1933) conducted certain cytological studies on kala-azar patients with the help of supravital staining technique and showed the importance of the reticulo-endothelial system in infection and immunity in kala-azar. It was found that within the animal body, *Leishmania donovani* are present only within histiocytes and that in untreated kala-azar cases there is an enormous increase in the histiocytic elements of the reticulo-endothelial system and a reversal of the normal monocyte-histiocyte ratio. During and after treatment a distinct drop in the number of histiocytes is noticeable and this is followed by a gradual restoration of the monocyte-histiocyte ratio to normal. Whenever antimony failed to bring about these cellular changes, the patient showed no clinical improvement. In experimental kala-azar in animals, such as mice and hamsters, the same sort of reduction in the number of histiocytes took place after treatment, but it was not followed by a rise in the monocytic elements. On the other hand, the histiocytes rapidly proliferated again and led to an intensification of the infection. This appears to suggest that the action of antimony in kala-azar is an indirect one through the reticulo-endothelial system. The impression gained is that three factors are at work in this indirect action, namely, (a) reduction in the number of histiocytes, within which alone the leishmania seem to live and multiply, (b) proliferation of monocytes leading probably to antibody production, (c) destruction of leishmania by lytic antibodies. The first (a) is probably due to alterations in cell permeability as suggested by Acton and Chopra, leading to their disintegration, and as regards (b) and (c) there is evidence that antibodies are formed in kala-azar, that they are associated with proliferation of monocytes and that they are capable of destroying leishmania, both *in vitro* and *in vivo*.

Arsenic. Various compounds of arsenic are used in the treatment of trypanosomiasis and spirochaetal infections. The mode of action of these preparations seems to be an

indirect one, like that of antimony compounds. The presence of arsenic within the reticulo-endothelial cells has actually been demonstrated by the silver impregnation method by Jiminez de Ausa and Kuhn (1928). Splenectomy experiments in spirochaetal infections have demonstrated that infections held in check in animals break out into acute manifestations in splenectomised animals and that treatment of these with specific drugs is not as effective as in non-splenectomised animals. Kritschewski and his colleagues (1927-28) have produced evidence to show that the mortality rate is increased and the cure rate greatly decreased after splenectomy and that an intact reticulo-endothelial system is necessary for the full therapeutic activity of compounds of arsenic. From these and other observations it may be suggested that the reticulo-endothelial system functions, (a) by serving as a depot for concentrating arsenical drugs, (b) by helping in the production of more efficient parasitocidal substances and (c) by increasing the amount of antibody produced and by bringing about destruction of parasites.

The control of immunity through the reticulo-endothelial system and the chemotherapy of syphilis has received much attention during recent years. It is probable that many of the prophylactic and therapeutic measures used in combating the toxic effect of arsphenamine have their seat of action in protecting or allaying the cells of this system. The reticulo-endothelial system through its property of phagocytosis is an important agent in the purifying mechanism of the blood, and it is also considered to be the chief source of antibody production. It is considered to be of great importance in intravenous therapy, for many materials injected into the blood-stream disappear from it quickly with deposition in the reticulo-endothelial cells.

Reticulo-endothelial system is believed to be bilirubin-producing apparatus. Marked bili-rubinæmia indicates hyperfunction of the reticulo-endothelial system and hypo-function of the liver, caused by the toxic action of either the syphilitic virus or the arsphenamine. This system plays an important role in the struggle against syphilitic infection, and the arsphenamine reaction as a group are largely referable to centres for localisation of reticulo-endothelial system in the liver, the suprarenal glands, the bone marrow, the capillary endothelium and the skin. Measures aimed at the protection of this system are important in the prevention of reaction to arsphenamine.

Bacterial and Virus infections

In bacterial and virus diseases no drug has so far been discovered that has any specific action on the causative organism and, therefore, our knowledge of the chemotherapeutic action of drugs used in these diseases is still very unsatisfactory. The beneficial results that are obtained in these diseases are chiefly dependent upon the natural resources of the body to combat disease. The best we can do in these infections, therefore, is to help the natural process at work, in one way or another. This has been attempted with a certain degree of success.

In the case of chronic infections, a large number of protein substances such as peptone, milk, muscle extract, vaccines and sera, and certain colloidal metals have been used to stimulate the natural responses of the body. Although our knowledge as to how these substances act is still very vague, yet there are reasons to believe that the therapeutic results obtained are probably attributable to a non-specific stimulation of the reticulo-endothelial system by these substances. It has been shown that serological alterations such as increase in titre of antibodies, and cellular changes such as leucocytosis and increased phagocytic activity of mononuclear cells, are noticeable after injections of these non-specific protein substances. There is evidence that these substances are concentrated in organs such as the liver, spleen and bone marrow; it is likely that through these organs an increase in the efficiency of the natural immune processes occurs.

The action of specific anti-sera used in the treatment of acute infections is chiefly a direct one upon the causative agent of disease. They either destroy the agents themselves or prepare them in such a way that other mechanisms of protection may destroy them subsequently. Specific vaccines, when injected into the body, are picked up by the reticulo-endothelial cells and result in the formation of specific antibodies which act as described above.

Conclusion. By way of conclusion we may state that evidence obtained from studies on the mode of action of drugs in

infectious diseases taken as a whole, strongly suggests that in the overcoming of infections the reticulo-endothelial system plays a part of no mean importance. The exact manner in which the system responds to the stimulus of treatment appears to depend upon the nature of the infective agent concerned. While certain parasites are readily destroyed by phagocytes, others require to be disposed of by the destructive action of lytic anti-bodies. The ideal response in the first case is a mobilisation and functional activation of the phagocytic cells of the reticulo-endothelial system, whereas in the second instance the best results are obtainable by increased antibody production. When either of these methods fails, the reticulo-endothelial system attempts to utilise other methods at its command, such as elaboration of powerful parasitocidal substances from the drugs used. From this there is every reason to believe that beneficial results of drugs are not due to one single factor but rather to a combination of factors. Which one of these factors plays the predominant part varies in each case. The specific drug is that which is capable of stimulating the natural processes concerned in the cure of disease, and in addition bringing about such changes by direct and indirect action on the parasite or its environment, as would be conducive to the success of the natural processes at work. If this is so, then it is easy to understand that a knowledge of the reticulo-endothelial system, which is the chief protective mechanism of the body, is essential not only for the proper understanding of infectious diseases, but also for the carrying out of successful treatment.

CHAPTER VI

PHYSIOTHERAPY

Physiotherapy is derived from a Greek word meaning 'nature cure' and is defined as "the use of natural forces, such as light, heat, air, water, and exercise in the treatment of disease." Probably the oldest forms of physical therapy are massage and the so-called "healing waters" or hydrotherapy. Light and heat therapy have been gradually introduced; during the past fifty years, electricity and radium have been added to this group.

The use of physical methods in therapy has received considerable attention of late years. As these methods are being employed with success in various diseases commonly occurring in the tropics it will not be out of place to briefly discuss them here.

HYDROTHERAPY

This term is used to denote the therapeutic procedures dealing with the external application of water at different temperatures over the whole or a part of the body. Hydrotherapeutic measures have been known for a very long time but were formerly practised on a purely empirical basis. It is, however, now possible to explain the fundamental principles involved in them from a physiological standpoint.

Indications. There are very few diseases in which hydrotherapy in some form or other is not capable of rendering some service. Hydrotherapy finds its chief application in diseases of the nervous system where it is perhaps more important than many medicinal agents. It has been employed from time to time for its sedative, tonic and antiphlogistic effects. The sedative effects are, however, the most important from the point of view of the physicians. In many circulatory diseases, the value of hydrotherapy has been more than once recognised. In cardiac neurosis and pseudo-angina, hydrotherapy has been widely used.

In respiratory diseases, its field of utility is well known. It has been employed whenever an antithermic, decongestive and antiphlogistic effects are sought. As a respiratory exercise, cold effusion or immersion of the face in cold water has been recommended. In cases of obesity, gout and other disorders of metabolism, hydrotherapy, combined with massage, has been found of great value.

Effects produced on the system. The main object of this therapeutic measure is to obtain a reaction in some definite direction and to serve some definite purpose. The effects produced are varied according to the temperature of the water used for the bath and may be classified under the following heads :—

A. On the nervous system. A tonic and stimulant action is produced in cases of depression, of sluggish function and of low blood pressure; a sedative and soothing effect is obtained in irritability of the nervous system. In cases of meningitis, cerebral hyperæmia, etc., an antiphlogistic effect is also said to be produced.

B. On the circulatory system. In the first stage, a peripheral vaso-constriction is produced with pallor and cooling of the skin. This effect lasts only for a short time. In the second stage a more prolonged effect is produced in the form of vaso-dilatation with a red flush of the skin and a sensation of warmth. The blood stream can be markedly influenced by hydrotherapeutic measures. The Vienna School of Winternitz has proved by tests on healthy human beings that cold baths of a short duration with friction or rubbing produce an increase from one million to one million and a half of erythrocytes and treble the number of leucocytes. They increase the hæmoglobin by 20 to 25 per cent.

Excessive cold produces local anæmia and if prolonged, ischæmia and death of tissues. Heat also acts in a similar manner. Short application of heat produces a local increase in the constituents of blood. By the application of stimulating measures to one area of the body, the blood can be diverted to this area and in this way congestion of other parts is relieved. Thus the use of the abdominal compress or girdle will reflexly relieve a congestive headache.

C. *On the respiratory system.* An increase in depth is always observed, and the rate is also somewhat increased.

D. *On the urinary system.* A temporary diuresis is produced.

The application of baths, hot or cold, should be followed immediately by reaction, in normal individuals. In the weak and feeble this reaction is delayed. If it does not occur or is incomplete the application of baths is inappropriate and should be modified. The reaction may be hastened by the application of cold after heat, by friction in the bath and by using chemical stimulants such as CO_2 and various chlorides in the water.

Hydrotherapeutic Measures

Compresses. **Hot compress:** This is very commonly applied in all kinds of inflammatory conditions. The method is very simple but should not be used indiscriminately. Unless used carefully, hot compresses in acute inflammatory conditions of a joint often bring about an impairment of function. Compresses should be applied as hot as the patient can bear and must be kept hot by frequent changes. They produce a local hyperæmia and, therefore, should never be applied to fresh injuries. They are efficacious in relieving spasm.

Cold compress. These are less frequently used. Due to the vaso-constrictor action of cold a beneficial effect is produced on recent injuries and inflammations.

Packs. **Hot pack.** These are used to facilitate elimination of toxins from the system. The water must be as hot as possible as the sheet taken out of the hot water cools off very quickly.

Cold packs. For the cold pack the water should be about 75°F. or less. The colder the water, the better the reaction. The wet pack has a very relaxing effect on the nervous system. It has been used very successfully on maniacs and in cases of chorea. The duration of the treatment is one hour but the treatment should be interrupted if the patient complains of chilliness.

Baths. Baths are of two different kinds—the hot bath and the cold bath. A good deal of confusion exists with regard to the temperature of the water used in the different forms of baths commonly employed. The following table will be useful.

Cold bath	..	40°—65°F	(4.4°—18.3°C). .
Cool bath	...	65°—75°F	(18.3°—23.8°C).
Tepid bath	...	85°—95°F	(29.4°—35.0°C).
Warm bath	...	95°—100°F	(35.0°—37.7°C).
Hot bath	..	100°—110°F	(37.7°—43.3°C).
Very hot bath	...	100°—120°F	(43.3°—48.8°C).

Cold bath. Cold baths are used to bring down the temperature in those fevers where antipyretics are not advisable. When using cold baths, two opposing factors must be considered. The colder the water the more rapid the passage of heat from the body surface, but cold water will also produce constriction of the cutaneous vessels and in this way the passage of heat from the interior of the body to the skin will be delayed. A balance must, therefore, be struck and in practice it is found that baths at about 69.8°F. or 21°C., are most efficacious in reducing temperature. The temperature once depressed does not rise again at once but remains low for hours. Cold baths are sometimes inconvenient from the point of view of the patient. In such cases cold sponging may be employed as it has a similar effect to cold baths and stimulates the nervous system. In typhoid fever when the temperature rises above 103°F., cold applications in the form of sponging are advisable and this should always be accompanied by friction of the skin which not only prevents chilling but also dilates the cutaneous vessels. During the initial stages of the fever the reduction of temperature is transient and slight. In the third week of the disease, however, when the temperature is beginning to show wider diurnal fluctuations, baths usually produce a much more marked and prolonged remission. Furthermore the remissions are most marked at times when the febrile temperature has a downward tendency.

Antipyretic drugs and cold baths in fever. A word may here be said about the relative value of antipyretic drugs and cold baths. Both these have their respective advantages and disadvantages. The chief advantage of a cold bath is that there is no danger of collapse, but this need not be apprehended if a proper drug is selected and the dose properly adjusted. The drugs may save the patient the exertion, discomfort and the shock which are attendant on a cold bath. In the case of baths, the temperature-regulating mechanism is not adjusted to normal and the patient feels all the ordinary effects of an attempt to reduce the temperature below normal, *i.e.*, chill, cyanosis, etc., and the metabolism is increased rather than decreased. The action of chemical antipyretics is more pronounced and lasting and resembles more closely that of natural defervescence. Barbour and his associates have shown that antipyretic drugs bring about dilution of the blood, which favours the dissipation of heat by radiation. Besides this their analgesic action is of great value in influencing the subjective condition of the patient.

The disadvantages of cold baths are greatly diminished if tepid baths are used. Although these have not such a marked antipyretic action, they have a more stimulant action, improve the blood pressure and digestion and promote sleep. The nitrogen excretion is increased. In prolonged fevers, such as typhoid, antipyretic drugs should never be used nor should they be combined with cold baths as they prevent the only thing which is essential, that is the reaction. The excretion of

antipyretic drugs takes place from the already overstrained kidneys in constant fevers, while the already disturbed stomach is irritated by their use. Antipyretic drugs further decrease oxidation and may interfere with the ordinary protective efforts of the body against disease. Besides, the fever will sometimes resist all doses of antipyretic drugs which can be given safely, while the temperature can be lowered by cold sponging or a bath. In septic fevers and tuberculosis antipyretics do harm by depressing the patient and producing increased perspiration. In these conditions cold bathing serves no useful purpose as the patient shows no reaction. In acute illness if the application of cold is impossible, these remedies may be given, but usually they are unnecessary, as unless the fever is prolonged it is not harmful. If these drugs are used they should never be pushed till toxic symptoms such as cyanosis are produced. If given in moderate doses they do not produce the desired effect, cold baths should be applied. In thermic fevers such as heat stroke, antipyretics are useless as they do not stop the rapid rise of temperature.

Hot bath. Exposure to mild degrees of heat, causes a dilatation of superficial vessels; but some compensation is attained through constriction of deeper vessels. The circulation rate is increased by about 29 per cent. It tends to decrease the load on the heart to a minimum. Exposure to higher temperatures, on the other hand, temporarily increases the work of the heart, possibly 30 or 50 per cent. or even more, but ultimately the subject gains. Such measures are desirable in some cases of circulatory disorders and they may prove useful by ridding the body of fluid or toxins through sweating.

Hot baths are indicated whenever elimination is desired and especially when kidney function is defective. They are used in various schemes of hydrotherapy in order to act upon the foci of inflammatory trouble, *e.g.*, in general muscular rheumatism and fibrositis, the heat of the bath helps to relax the parts thereby restoring them to a healthy function. The use of these baths in cases of anaemia is also indicated. These baths are contraindicated in all forms of heart disease, in general weakness and when there is inclination to hæmorrhage. Plain water may be utilised for this purpose, or hot mud and peat baths. Massage is sometimes very useful along with these baths.

Generally, various methods of hot air or vapour baths are available of which the following may be mentioned as being the most common:—

Turkish baths. These consist in the exposure of the unclothed body to dry heat at varying temperature (up to 250°F. or more) for 20-30 minutes. By this means abundant perspiration is induced and thereby toxins are eliminated. It is followed by massage, douching, and rest for an hour or so during which an abundance of plain water should be drunk.

Russian baths. These are very similar, but the air is saturated with water vapour and, therefore, the temperature cannot range so high. Perspiration is induced more rapidly, and the bath is of shorter duration.

In both of these the object is to induce rapid elimination of toxins and other poisons and at the same time to assist in maintaining the free mobility and function of the various parts of the body by massage. Either may be used advantageously as a routine preventive of gout or rheumatism, especially by those who are unable to secure suitable exercise.

Spray bath. Application through a large perforator or rose nozzle of a continual fresh layer of water in a finely divided state with a certain mechanical impact on the skin constitute the main principle of spray baths. This removes secretion and has a marked sedative effect on the nerves. It is very useful in sunstroke, either alone or combined with ice rubbing; in typhoid fever the combination is especially efficient.

Tepid sponging. This is best given late in the afternoon or towards evening, the water used being at about 65°F. The face and neck are first dealt with by applying cold compress at 60°F. to the head after sponging. Sponge downwards exposing only the part being sponged. After the whole body has been gone over, the patient is dried thoroughly, wrapped in warm blankets and left for an hour or so. A moderately sedative effect with abstraction of considerable heat is produced by these means. They are particularly indicated for old people with arteriosclerosis in whom a strong stimulus must be avoided and who need a stimulation of the peripheral vascular system. They are useful in febrile cases who are too sick to be moved about and they can be repeated any number of times.

Medicated baths. Medicinal agents in some form or other may be mixed in the baths. It is not definitely known whether these produce any special effects though positive claims have been made by various workers. Alkaline baths, sulphur baths, etc., have been frequently employed for these purposes.

MINERAL WATERS

The therapeutic qualities of mineral waters have never been fully appreciated by the medical profession in India though their virtues have been empirically known for a long time. In England and on the Continent of Europe, famous spas have developed by the side of hot and mineral-water springs and people are taking advantage of their healing effects. No rational explanation was given regarding the properties attributed to these waters. Since the discovery of radium, however, it has been contended that some of these waters are radio-active, which may probably explain their physiological activity. Others assert that the presence of traces of rare elements in these waters is responsible for their action. Recently, a hormone of the nature

of œstrin is said to have been found in the mud spas like Frazenbad and it is likely that other hormones may be present. Different kinds of enzymes have also been detected. Besides the hygienic and climatic factors all these various ingredients of the soil occurring in solution are responsible for the therapeutic effects produced by these spas.

For the treatment of tropical invalids suitable spas should be selected. The following points may be carefully considered :

1. *Climate.* A good sunshine record is essential, with protection from cold winds.

2. *Altitude.* This, for the majority of patients, should be several hundred feet above the sea-level.

3. *Sub-soil.* Adequate drainage is essential if chills are to be avoided and patients enabled to be as much in the open air as their condition permits.

4. *Waters.* These must be suitable for the treatment of intestinal complaints, derangements of the liver and other digestive organs and for restitution of the blood-forming organs.

5. There should be abundant facilities for recreation and exercise which play a very important part during spa-treatment.

Therapeutic effects of mineral waters. The radio-active thermal waters are remarkable for their low mineral content, but the mineral elements are in a high degree of ionic dissociation and possess different chemical activity from that produced by artificially produced solutions of the same salts. Diuresis is the most conspicuous effect of drinking these waters, and is much greater and more rapidly produced than with a similar quantity of distilled water, a fact which has been frequently demonstrated by experiment. The chlorides, urea, uric acid, etc., are also excreted in increased amounts. In gout, mobilisation of the stored up uric acid occurs, and it appears during the first few days of treatment in increased quantities in the blood, with the result that an acute attack of gout is not uncommon when treatment is started. Later, the blood uric acid falls, and a long period of freedom from attack follows. The chief sphere of usefulness of the radio-active thermal waters is in gout, subacute rheumatism, fibrositis and neuritis.

The muriated or sodium chloride waters, with the addition either of carbon dioxide, bicarbonate of soda, the sulphates of sodium, calcium and magnesium, or sulphur, are mainly used in the treatment of digestive disorders. The principal diseases of the digestive tract which are successfully treated include the various functional dyspepsias, reflex dyspepsias (from cholecystitis, gall-stones, chronic appendicitis, etc.), chronic catarrh of the stomach, early cirrhosis of the liver, constipation and irritable conditions of the colon. The alkaline waters enjoy a great reputation in the treatment of catarrhal states, but are contraindicated in atonic dyspepsias. Carbon dioxide and sodium chloride (muriated) alone have been found to increase the secretory activity of the stomach, whereas the sulphated alkaline waters of Karlsbad and Marinebad, in spite of their carbon dioxide and sodium chloride content, tend to diminish it. It thus follows that in disorders associated with hyperchlorhydria and hypertonia, the simple alkaline and sulphated alkaline waters are indicated, whereas in the opposite condition the best results will be obtained from simple gaseous waters (radio-active), or very weak muriated, or muriated alkaline ones. In the nervous dyspepsias, the exact action of the water on the secretion is of little importance compared with its general tonic and stimulating influences.

In the treatment of liver disorders, which include congestion and enlargement, due to over-eating, alcohol, cardiac failure, malaria, cholelithiasis, cholecystitis, catarrhal jaundice, and that undefined disorder biliousness, which has a very real existence in general practice, the muriated waters, both alkaline and sulphated, and the sulphur waters, are used. They all tend to dilute the bile, promote a free flow, and dislodge concretions.

The stronger muriated and sulphated waters are not as a rule taken at spas, but are bottled and exported for use in the patient's home. By their hydragogue and cathartic action they are indicated in cases of congestion, and produce free watery stools, but they should never be used in cases of catarrh of the bowels.

Chronic diarrhoea (often of tropical origin) will usually benefit from suitable spa treatment. When associated with portal congestion, the mildly aperient waters of Cheltenham and Leamington are particularly indicated, while in other cases, the simple thermal, sulphur or calcareous waters will produce better results.

Chronic constipation is extensively treated by mineral waters. The strong sulphated and muriated waters should only be used in stout plethoric individuals, since they produce free watery evacuations and deplete the portal system. In persons of weaker physique, the milder muriated and sulphur waters are to be preferred. They are usually prescribed before breakfast, and followed by a short walk.

Hæmorrhoids are often treated by mild aperient waters, but they are said to respond particularly well to sulphur waters, and the wide use of sulphur therapeutically in this common complaint would appear to support the claim. The sulphur waters, also owe their aperient action largely to the other mineral constituents present. The sulphur present is considered to exert a special action upon the liver. The weaker sulphur waters have an aperient action only when taken in large quantities; this again being due to the action of the salts present. Otherwise, they are merely solutions of sulphuretted hydrogen and carbon dioxide.

Where the simple alkaline waters are not available their place is taken with equal advantage in most cases by the alkaline muriated water. They contain sodium bicarbonate with varying quantities of CO_2 . They are diuretic and are useful in gout, glycosuria, dyspepsia of the hypertonic type and in liver disorders.

The chalybeate waters are of two chief kinds, the one containing carbonate of iron, and the other sulphate of iron. These chalybeate waters are easily assimilable, are not constipating, and so are valuable in the treatment of dyspepsias due to anæmia and debility. They might with advantage be more widely used.

It is usual for mineral waters to be taken on an empty stomach and where an action on the stomach or bowel is

important, the chief drinking is done before breakfast. The dose will vary with the strength and character of the water, the type of patient and malady to be treated, and is usually from half a tumbler to five or six tumblers. Later, in the day, the same or other mineral waters may be taken according to the resources or custom of the spa. For instance, an aperient water may be taken before breakfast, and a mild saline to stimulate the gastric functions before lunch and dinner; or a mild chalybeate water for tonic purposes may be ordered for the later doses. It is usual for short walks to be taken between successive glasses of water, and beautifully laid out gardens and walks are an important part of the armamentarium of the spas.

Modifications of the water may be made under certain conditions. If hot, it may with advantage be cooled, while on the other hand, the heating of some of the cold mineral waters increases digestibility and absorption. The heating of radio-active, gaseous waters, however, materially alters their composition, and they should always be drunk in a fresh state at the spring, if their specific action is required at its maximum. In the milder waters, which have little or no aperient action, purgative salines are often added, while in other cases, a useful modification is obtained by the addition of effervescent alkaline compounds.

A complete list of mineral waters occurring in Europe and India will be found in the appendix.

ELECTROTHERAPY

General considerations. Any form of physical energy applied to the body will produce first a physical effect, and this in turn will be transformed into some form of physiological activity. It may serve to stimulate function, promote metabolism or relieve pain. If applied beyond the degree of physiological toleration, destruction of tissues will occur. The primary physical effects of electrical energies applied to the body are either thermal, electro-chemical or kinetic. The clinical use of thermal effects by high frequency currents in the form of medical and surgical diathermy has been in the foreground of medical

interest during recent years. Galvanic and faradic currents in different forms have also a wide field of utility.

Galvanic current. When applied to the human body through suitable electrodes, the galvanic current produces primary physico-chemical effects (1) at the point of contact of electrodes (polar effect), an acid reaction at the positive pole and an alkaline reaction at the negative pole. There is also (2) a change in the electro-chemical concentration of the tissue fluids in the path of the current (inter-polar effects). The physiologic sequence of the chemical changes produced by the galvanic current is tingling and pricking under each electrode and a feeling of gentle warmth in the area treated. After a treatment, when the electrodes are lifted off, there will be a visible hyperæmia of the skin corresponding exactly with the area covered by each electrode; this represents the dilatation of capillaries of the skin produced by the mild chemical stimulation of the current. This 'counter-irritation' is accompanied by increased local circulation and nutrition of the parts between the electrodes. This improvement in the circulation and consequent relaxation of the tension of the tissues is probably responsible for the relief of pain by galvanic current.

Faradic or static current. The static current is peculiar in that it is of high voltage and of extremely low milliamperage. The current is specially useful as it produces a pronounced decongestion in tissue. It is used in the treatment of neurasthenia, general or nervous debility or neuralgia. It is of use also in acute myositis and in the absorption of inflammatory exudates from the joint. The galvanic and faradic currents are employed, both generally and locally for their stimulating action.

Locally, the galvanic and faradic currents find their chief employment in cases of muscular paralysis, both to prevent degeneration or atrophy, when nervous control has been lost, and to build up healthy muscular substance when atrophy has occurred from disuse. The *sinusoidal current* is perhaps the most useful to employ in the earlier stages; in this the current is continuous, but is made to vary in strength in a smooth and wave-like fashion without sudden interruptions. Later, the interrupted galvanic current is more useful, and is often the only one to which response can be obtained, whether before operation or in the earlier stages of repair. The current must be made and broken at regular intervals, a metronome introduced into the circuit being a useful contrivance. Failing this, the patient may be instructed to remove and replace one of the terminals at regular intervals, thereby stimulating his interest in his own case. When once a response is obtained to the faradic current after an operation for nerve-suture, this type of electricity should be substituted for the galvanic current as being more effective.

In therapeutics, electricity is employed in various ways:—

(1) **Electric bath.** In this patient lies in water to which a small addition of salt is made, and through which a galvanic current is passed. The effect of this is to increase the superficial circulation and produce cutaneous hyperæmia. It is often useful in diffuse rheumatic and gouty fibrositis, as also in conditions in which the general muscular and nervous tone of the body has been lowered. It is of considerable value in the treatment of conditions depending on arterial spasm, such as Raynaud's disease, and also to prevent chilblains in paralysed limbs. Care must be taken only to increase or decrease the strength of the current gradually, otherwise the patient may experience an unpleasant shock.

(2) **Electrolysis.** This is used chiefly for the destruction of superfluous hairs, moles, etc., and the treatment of nævi, where excision is undesirable. The passage of a current of sufficient strength, between metallic poles actually inserted into the tissues sets up an electrolytic action, and coagulation of the blood or local destruction of hair follicles results. Organisation of the thrombus leads to obliteration of the vascular spaces and the disappearance of the tumour. The clot formation is most marked at the positive pole; hence it is often unnecessary actually to insert the negative needle into the tissues, but to use an ordinary flat pad moistened with salt solution and applied to the skin away from the part to be treated. At the negative pole a caustic alkaline compound is formed which may lead to sloughing of the tissues and scarring.

(3) **Ionization or ionic medication.** Ionization, ionic medication or cataphoresis consists in the introduction of chemical substances or drugs directly into the living tissues of the body by means of an electric current. Other terms like 'iontophoresis' or 'percutaneous' electro-osmosis' have also been used in different countries to describe the same form of medication. It is interesting to note that ionisation is not a new development in therapy, as is generally believed, but was enunciated as early as 1747. Palaprat claimed to have introduced iodine into the tissues in this way in 1833, and there are numerous references in the literature from that time onwards. During recent years, interest in this subject has been revived by the work of Professor Ledue of France.

Principle of therapy. In solutions containing acids, bases and salts, the molecules of these divide into positively and negatively charged ions even without the flow of any current. When a galvanic or direct current passes through such a solution, it causes a migration of the ions, in accordance with the polarity of the current. Ions with a positive charge—zinc, copper, quinine, cocaine are repelled by the positive pole; those with a negative charge, like iodine, chlorine, salicylic acid, are repelled by the negative pole.

If the human body is interposed in the circuit instead of a solution of a salt in a vessel, and pads soaked in a solution of a salt or drug, are placed between the skin and the electrodes, kations at the positive pole and anions at the negative pole will enter the tissues and be disseminated in them. Prof. Ledue's classical experiments of producing strychnine poisoning in rabbits by driving it into the tissues by an electric current proved that drugs do penetrate the tissues by this method. Modern clinical and experimental evidence has, however, shown that ionic medication is of specific value only in pathologic changes of the most superficial tissues, as ions entering the body, are deprived almost immediately of their charge by the electrolyte salts of the body fluids, the blood-stream and lymph. The much-heralded beneficial effect of ionization on arthritis, etc., was found to be attributable to the passage of the galvanic current itself and not to any ionic medication, and the difference in reaction of the skin was shown to be due to difference in counter-irritation by the specific drug.

Depth of penetration of ions. The depth of penetration of the ions such as zinc, copper, silver, may be estimated with the naked eye, the depth of staining being an accurate indication. Zinc usually shows a white colour about the needle and in the softer subdermal tissue, the extension will be noticed over a large area. In granulation tissue, a still greater penetration is noticeable. The degree of diffusion depends upon the strength and duration of the current, which must depend upon the toleration of the patient. Ordinarily a current of 3 to 4 milliamperes per square centimetre of the surface, maintained for 10 to 15 minutes, can be tolerated without any inconvenience by patients. In certain cases, stronger currents are required to drive the ions into the tissues. Under these circumstances, anaesthetics have to be used to benumb the parts before the process of ionization starts.

Drugs used for ionization. Ionization has been carried out with a large number of drugs. Zinc, copper and silver ions have been most frequently utilised. Heavy metals like mercury, magnesium and lead have been successfully driven into the tissues. Potassium ferricyanide, ferrous sulphate, arsenious acid, iodides, etc., have also been used from time to time. Quinine, cocaine and adrenalin are less frequently used.

The solutions of the drugs employed for ionization should be well diluted, otherwise dissociation of the ions does not take place readily. One to two per cent. solutions are usually employed by most workers, but this has to be varied, using the tolerance of the patients as a guide. Compound solutions of iodine have been diluted from 5 to 20 times according to the sensitivity of the skin or the mucous surfaces.

Therapeutic possibilities. Ionization with different chemicals and drugs has been employed in chronic arthritis, sciatica, lumbago, etc., with success. In the treatment of sinuses, chronic ulcers, rodent

ulcers, lupus, warts, and neuritis, potassium iodide and sodium salicylate have been used and the reports certainly indicate that the method deserves further trial. Copper ionization is used to make sluggish wounds such as varicose ulcers to heal. It is also useful in chronic endocervicitis, a strong current of 10 to 12 milliampères being used for 20 minutes. Zinc ionization is useful in chronic otitis media, intermittent nasal obstruction, ethmoiditis, oriental sores, etc., but the benefit is often temporary. Chlorine ionization serves to loosen superficial scars. Dense superficial scars, if not too extensive, are made pliable and thus readily amenable to subsequent mechanical stretching by massage and other means.

In dermatology, ionic medication has got many supporters and this form of therapy is practised to a fairly large extent. Shaffer has used iodine solution in coccigenic sycosis, dermatitis, papillaris capiti, lupus erythematosus, pruritus ani and verruca. Arsenious acid has been used by others in psoriasis and copper ferricyanide for ringworms. In skin actinomycosis, iodine solution has also been employed by ionization.

(4) **Diathermy.** The term diathermy or 'heating through' means the passage of a special kind of current through the body. During the passage, heat is generated in all parts traversed by the current, so that the tissues are heated directly, simultaneously and throughout. Many terms have been used by other workers, in place of diathermy, such as 'thermo-penetration,' 'transthermy' and 'endothermy,' but the first one is now established and most widely used. When other methods of heating are employed, the heat never penetrates beyond a certain distance from the skin, *i.e.*, epithermy is produced.

In order to produce diathermy, an electric current which alternates at an exceedingly rapid rate is used. Such currents are commonly known as 'high frequency' currents. Its main characteristic is that it does not stimulate the excitable tissue nor cause any chemical (electrolytic) changes and, therefore, it can be raised to a strength sufficient to generate perceptible heat. In order to do this the current must reverse at a certain rate per second which depends on its strength; the stronger the current, the higher should be the frequency of oscillation. But there is a critical height, beyond which the current loses its stimulating and electrolytic powers, whatever the strength may be. The height of its frequency of oscillation cannot be definitely stated but it may be regarded as not less than 500,000 per second.

The diathermy current does not distribute itself like the constant current. Its path and distribution depend on the resistance of the conductor, its capacity, the self-induction that takes place in the conductor and the frequency of oscillation. The position of the electrodes is also very important

Medical diathermy. By it is meant the use of the high frequency oscillatory current, to produce heating through the body in disease. It may be local or general.

Surgical diathermy. The term has been used by English authors to denote the use of the high-frequency current for heating abnormal tissue to a degree high enough to coagulate or boil the fluid within it. But this is only one amongst the various uses of the high-frequency current in surgery at the present day. The term surgical diathermy is not a comprehensive term and it is better to include all the methods under the heading 'Electrothermic methods of surgery.' These methods are employed to destroy and remove new growths, both innocent and malignant, and infective granulomata. The main advantage is that the effects are obtained without disturbing anatomical continuity. There is no risk of hæmorrhage or of artificial metastasis and dissemination of infection.

Therapeutic uses of diathermy. The therapeutic effects are those of heat. It is, therefore, valuable in the relief of congestion and chronic inflammation where it acts by inducing hyperæmia and acceleration of blood and lymph-flow through the affected part.

Pain due to congestion or neuritis, is often relieved by diathermy and it is much more effective than surface heating. Pain associated with muscular spasm is also relieved by diathermy, as in cases of fissure of the anus and hæmorrhoids.

In cases of dysmenorrhœa of the painful contraction or congestion type, diathermy is very useful and its application to the interior of the pelvis for a few days before the onset of the menstruation often renders the period painless.

Cases of high blood pressure are effectively treated by diathermy. It lowers the blood pressure and alleviates the accompanying symptoms. Very likely the heat produced lessens the viscosity of the blood and thereby lowers the peripheral resistance. It also lessens the tone of the arterioles. The heart is thereby relieved of some of its work. It is also useful in the following cases: (1) Diseases of the urogenital organs in women, e.g., gonococcal urethritis and endocervicitis, infective endometritis, salpingitis, erosion of cervix, parametritis and perimetritis. (2) Diseases of urogenital organs in man, e.g., gonococcal prostatitis, and vesiculitis, gonococcal epididymitis and orchitis, urethritis. (3) Diseases of joints, bones and fibrous tissues, e.g., arthritis or osteoarthritis. (4) Diseases of the nervous system, e.g., peripheral neuritis, paralysis agitans, anterior poliomyelitis, neuralgia associated with herpes zoster, trigeminal neuralgia, metatarsalgia, coccydynia, fibrositis, angina pectoris, intermittent claudication, Raynaud's disease, chilblain, acrocyanosis, have been treated with good results.

Diathermy should not be applied to regions from which hæmorrhage has occurred or is likely to occur. Some authorities are of the

opinion that diathermy is inadvisable in acute infections and recent injury. It should not be applied during menstruation, there is a risk of increasing the loss of blood. Anæsthesia of the skin is a contra-indication. Due to the loss of power of perceiving heat the patient may fail to give information when the degree of heating is definitely damaging to the tissue.

Methods of application. These are:—(1) Local diathermy. (2) General diathermy. (3) Labile method of diathermy, *i.e.*, by moving the active electrode over the region to which diathermy is being applied. (4) Combination of diathermy and massage.

Dosage. In the present state of our knowledge it is difficult to lay down any precise rule. For the production of sedative effects weak current should be used in the earlier stages of infection or injury and the duration should be relatively long. As the case progresses the degree of diathermy may be increased and its duration shortened. In all cases where there is any doubt it is always safe to commence with a small degree and apply treatment for a longer time. The temperature of the skin or mucous membrane and the time for which the rise of temperature is produced are the only accurate measures of dosage.

RADIATIONS IN THERAPY

Radiation means the transference of energy by means of vibrations propagated in the ether at a velocity of 3×10^{10} cm. per second. The electro-magnetic theory of Faraday and Maxwell regards these vibrations as oscillatory changes of the electric charge and magnetic induction. Modern sub-atomics requires that radiant energy should be propagated in empty space in discrete, undivided 'quanta' and that any atomic resonator must absorb a whole quantum or none.

The following is a resume of the position regarding the action of the various forms of radiation; taken from Clark's *Applied Pharmacology* 1933.

Electro-magnetic radiation. There are different forms of electro-magnetic vibrations, *viz.*, Hertzian waves, radiant heat waves, the rays of visible light, ultra-violet waves, X-rays and the gamma rays produced by radio-active substances. The property which differentiates one kind of electro-magnetic radiation from another, is that of wave length. Only those with short wave lengths have the property of producing some physiological effect on the living tissue, and the shorter the wave length, the more marked is the effect produced. Radiant heat has been employed in therapeutics to produce local vaso-dilatation, while the visible light rays stimulate the retina. It is only those vibrations whose wave

lengths are shorter than those of the visible light rays are of importance in their therapeutic action.

The electro-magnetic waves form a continuous series between two extremes of wave length, *viz.*, 30 kilometers (Hertzian wave used in wireless telegraphy) and 10^{-10} cm. (gamma rays). But there is a marked difference between the power of penetration of light waves and X-rays. The passage of light waves through a media depends upon the arrangement of the atoms in a molecule, whereas that of the X-rays or gamma rays is solely determined by the nature of the atoms. In other words, the light waves are stopped by molecules, and X-rays and gamma rays, by atoms. On account of this curious behaviour, the relation between wave length and the ease of absorption is rather peculiar. The shorter the wave length of the light waves, the lesser is their penetrative power, while on the other hand, the shorter the wave length of the X-rays and gamma rays, the greater is their penetrative power.

Light sensitisation. There are certain substances in nature, which act as photo-sensitisers and which have the remarkable property of sensitizing the body in such a manner that the ordinary visible light rays produce the same effect as the ultra-violet radiations. For instance, paramocia are not affected by acridine dyes in the dark, but are readily killed when exposed to light. Haematoporphyrin acts in a similar manner and it has been shown that exposure to light subsequent to injections of haematoporphyrin produced an intense oedema of hands and face. Smallpox, pellagra and certain other diseases associated with excretion of porphyrin produce sensitisation of the skin to light and much of the damage that is done to the skin, can be averted if the patient is completely protected from all actinic rays.

Ultra-violet lights. For all practical purposes the ultra-violet radiations are divided into the near ultra-violet radiation (wave length between 3,900 A.U. and 3000 A.U.) and the far ultra-violet radiations (wave length less than 3,000 A.U.). The near ultra-violet radiations are not of much physiological importance, those lying between 3,000 A.U. and 2,800 A.U. have some therapeutic value. They produce in man, tanning of the skin and also activates ergosterol in the skin, and thus produce anti-rachitic vitamin. The direct action of ultra-violet radiation on man is due entirely to their action on the skin and the blood passing through the skin. Over-exposure to the ultra-violet radiation causes severe burn in the skin and inflammation of the conjunctiva. The effect usually appears some hours after the exposure. Ultra-violet light also causes contraction of plain muscles and exerts a bactericidal action on the micro-organisms.

It produces histamine in tissues, and this may explain the burns produced in the skin and contraction in plain muscle. Excessive exposure to ultra-violet radiation insufficient to produce burns, may produce general toxic reaction. Some of the symptoms produced are headache, malaise, tachycardia, rise of temperature, and insomnia.

The available source of this energy, in nature, is entirely traceable to sun light. Sun light contains ultra-violet rays extending from $290\mu\mu$ to $380\mu\mu$ approximately from $380\mu\mu$ to $780\mu\mu$ of visible light and from 0.78μ to 3.0μ of infra-red rays of fairly high intensity. But most of the ultra-violet rays from the Sun are absorbed in the atmosphere and the pollution above the towns absorbs a large proportion of both the visible and ultra-violet rays. Through clear air, ultra-violet rays down to 2,970 A.U. penetrate during summer and down to 3,060 A.U. during the winter. The chief artificial sources of ultra-violet radiation are mercury vapour arc-lamps enclosed in quartz, and carbon arc-lamps either bare or shielded with quartz. These artificial sources produce the radiations of far greater intensity than sun light and therefore, great care need be exercised in their application.

Ultra-violet radiations, whether obtained from nature or from artificial source, are powerful therapeutic agents. Our knowledge regarding their action is very imperfect. The limit of the wave lengths that produce beneficial effect is not well known, but probably it lies between the wave lengths of 3,500 A. U. and 2,800 A. U. The therapeutic properties are in the main limited to conditions of growth or of functions that are below normal. For example, it has been found to increase body weight to increase the rate of growth, to improve the mineral content of blood, to increase the functional activity of the endocrine glands, to increase the bactericidal power of blood, etc., where these are below normal. Rollier in 1903 commenced the treatment of tuberculosis other than the pulmonary type. His method commences with the exposure of the feet to the Sun for a few minutes each day, gradually increasing both the time and the area exposed until finally the whole body of the patient is exposed to the Sun for several hours daily. Perhaps it is true that at the present time the best guide to dosage is the degree of erythema which results after a test exposure, since most other methods take no account of the idiosyncrasy of the patient.

The experience goes to show that non-pulmonary tuberculosis rickets, malnutrition, and certain skin diseases respond well to treatment. Two mechanisms, which have a chemical bearing, have been suggested for curative process—(a) the photosynthesis of vitamin D and, (b) an increase in the bactericidal power of the blood. As a working hypothesis it may be assumed that ultra-violet irradiation helps to regulate calcium-phosphorus metabolism by means of the forma-

tion of vitamin D and at the same time increases the resistance of the blood to noxious bacteria. The evidence available at present is so contradictory and the matter is so obscured by controversy that it is impossible to form any definite estimate as regards the action of ultra-violet therapy on general health and disease.

X-rays. Whenever rapidly moving electrons hit matter x-radiation is generated. The exact nature of x-rays still remains in doubt. Whether the x-rays have a chemical or electrical or mechanical influence on animal tissue, is not yet fully understood. The effect produced by x-rays depends on three primary facts: (1) the intensity of the rays, (2) the duration of exposure and, (3) the wave length of the rays. The changes produced vary within wide limits with the susceptibility of various groups of cells. The group of cells most sensitive to x-rays, are the lymphatic tissue, and glands, the leucocytes, ovaries, testes, the suprarenal and various other glands with internal secretion, like the thyroid, the thymus, spleen, etc. Considerably less sensitive are the skin, the mucous membrane, the hair follicles, the kidneys, etc. The cells of the muscles and bones are the least sensitive. It is supposed that those cells, which are near the stage of sub-division, are the most vulnerable.

Reactions and dangers. X-rays in sufficient dosage produce slight temporary erythema and a temporary falling off of the hair. The changes produced by x-ray exposure do not become noticeable immediately after, but microscopic and chemical analysis may reveal changes within half an hour after exposure. When the tissue has been exposed to moderate doses, which will cause erythema to appear a week after, a faint redness and a slight itching or a burning sensation are noticed within a short time. With doses of sufficient strength, the irritation becomes so violent that even organs like skin, become atrophied and shrink or when exposure is excessive, ulcers and abscesses form. The administration of x-rays over large areas of the body sometimes produces a general reaction. The x-ray sickness forms a definite syndrome characterised by headache, loss of appetite and, in more severe cases, vomiting and diarrhoea. These toxic effects are readily induced after irradiation of the

abdomen and especially of the liver region. They are probably due to the injurious action of the x-rays on the mucosa of the alimentary tract and on the liver. The effects may possibly be intensified by ozone and other gases produced by the spark and discharge.

Units of x-ray dosage. The accepted unit for biological effect is that dose which will produce erythema of the skin and this is known as the unit skin dose (U.S.D.). The erythema dose as a unit is rather inconvenient, because it takes some time before the results show. It is also insufficient, because it shows only the intensity of the rays which prevailed on the skin, but does not indicate the intensity of the rays which penetrated to objects 6 to 10 c. cm. below the skin. It is, therefore, necessary to employ electrical or chemical quantimeters which enable us to determine the dose during the exposure on the skin, or at various depths below it. There are various chrono-radiometers which measure the colour change produced in chemicals by x-rays. The duration of the exposure which is necessary to produce a U. S. D. depends on many factors. The most important are the voltage, milliamperage, focus skin distance and filter. It is also influenced by the type of apparatus which is used. The actual time for the U. S. D. must be found experimentally for each apparatus.

Therapeutic application. X-rays are now the therapy of choice in many diseases of the skin. They are of importance in ear, nose and throat diseases, in exophthalmic goitre, and in the treatment of tumours in brain. In blood affections, such as leukæmia, in neuritis, in neuralgia, and in cases of arthritic joints they are applied with some success. The biggest field, however, is in gynecology. In the treatment of excessive hæmorrhage due to approaching climacterium or to fibroids or myomata, cure is achieved by exposure to x-rays lasting not more than $1\frac{1}{2}$ to 2 hours altogether. The cells of malignant disease may be killed or at least paralysed by doses of x-rays, but their value in the treatment of carcinoma is still doubted. The depilatory action of unfiltered x-rays is utilised in the treatment of ring worm of the scalp and occasionally in sycosis. X-rays are also used to reduce the sweat secretion in hyperhidrosis and to destroy both benign and malignant tumour of the skin. When the part of the body to be treated is situated below the skin, the application of x-rays is termed deep therapy. There are two types of deep therapy—medium deep therapy and deep therapy.

X-rays for medium therapy are not used as a destructive agent but are employed to set up certain biological changes or only a partial destruction of cells. In the case of deep therapy x-rays act as a destructive agent and are employed in localised conditions in deep-seated organs, carcinoma of the uterus, cervix, etc. To obtain the desired effect the cells of the growth should be actually destroyed. The doses should, therefore, be larger and the radiation should be penetrating that it may arrive at its goal in sufficient intensity without being heavily absorbed before it gets there.

X-ray diagnosis. The application of x-ray photography to diagnosis depends on the relative opacity of bone and flesh to the passage of the rays. The use of bismuth salts as an opaque lining for showing up the alimentary canal, of red lead for rubbing the finger tips for recording the design for finger prints are interesting side lines. The x-rays are readily arrested by atoms of high atomic weight, and suspension or solution of inert substances containing atoms of high atomic weights are introduced into certain body cavities and x-ray photographs are taken. Barium sulphate and bismuth salts are used as test meals for the study of the alimentary tract. Sodium tetra-iodophenolphthalein is used to render the gall bladder and biliary tract opaque and iodised fats or oils are injected intrathecally to permit photograph of the intrathecal space. Certain complex iodine compounds (Uroselectan B), which are readily excreted by the kidneys, are used radioscopy of the urinary system.

RADIO-THERAPY

In recent years radium has come to be used extensively in medicine. The fascinating history of the use of radium dates back as early as the times of the Romans. Some of the Roman spas were credited with the power of containing mystic cures. In the United States of America, the spring water of Saragota was said to have the power of curing various ailments. In Europe the district of St. Joachimstal earned a reputation owing to the healing power of its earth. People from different parts used to flock to the place to take the water, or to breathe the air in the mountain groves. Later, in the eighteenth century, attention was diverted to some Austrian springs. The wonderful healing property of the water of these springs was ascribed to electrical effects. In 1835 Burckhardt

Eble stated that this water contained a gas which was later proved to be nothing but radium emanation.

In 1896, Mme. Curie working in her laboratory in Paris, discovered radium and separated it from St. Joachimstal ore and since then the so-called mystic 'cures' that were ascribed to many spring waters and ores, were definitely known to be due to the presence of radium, which has now secured a lasting place in the realm of scientific medicine.

Nature of radio-activity. A radio-active substance has been defined as a substance which possesses "the property of emitting spontaneously radiation capable of passing through sheets of metal and other substances opaque to light and having the power of imparting electrical conductivity to the air." Radium is the most important member of the radio-active substances. It is a bivalent element closely related to barium. Radium is marketed in the form of soluble bromide or dichloride, because in the metallic state it undergoes rapid chemical alteration. Radium and other radio-active substances owe their radio-active property to spontaneous disruption into simpler atomic bodies and emitting certain emanations during this process of decay. These emanations are accompanied by the generation of rays which produce destructive or irritating effects.

The decomposition is spontaneous and goes on steadily at the same rate, the temperature and chemical composition being changed without producing the slightest visible effect. Other radio-active substances are thorium, uranium, ionium, solonium.

Disintegration of radium. Radium is constantly undergoing atomic decay and during the disintegration it produces three types of rays—the alpha, beta and gamma rays. This breaking up process is going on at a slow rate; roughly one atom in every hundred thousand million atoms blows up in one second. If we start with a certain number of atoms of radium, they will gradually become less and less. As the quantity of a given radio-active substance gets less, the actual number of atoms decomposing per second will also be fewer. It has been estimated that a radio-active substance will fall to half its original value in about 1,690 years. The first substance produced by this gradual decay is a gas called *radon*; it does not enter into chemical combination but is radio-active and decomposes in its turn, the time to decay to half-value being 3.86 days. From radon a whole series of radio-active substances

originate, mostly of short life, with successive losses of alpha, beta and gamma rays. These are radium A, B, C, D, E and F, the most penetrating rays being given off by the C group.

Varieties of rays—Alpha rays. In the decomposition of radium a fragment of the original atom is projected at a high speed carrying a positively charged helium atom. This is what is known as an alpha ray. The alpha particle is a bulky body and is rapidly stopped when it comes into collision with air or any surrounding structure. A screen or tissue-paper or a layer of varnish can cut off all the alpha rays, and in actual radium therapy needles are made of platinum so as to cut off all the alpha rays. The maximum distance through which the alpha rays can travel is 0.09 mm.

Beta rays. These are electrons, carrying negative charges of electricity. The beta rays are more penetrating than the alpha rays owing to the small size of the particle, the maximum speed through soft tissue being 2 cm. They can penetrate through several thicknesses of paper or thin sheets of metal or glass; most of them are, however, stopped by 2 mm. of aluminium, 1 mm. of lead or 5 mm. of muscular tissue.

Gamma rays. These are true radiations. They are electro-magnetic vibrations in ether and are similar to x-rays but of shorter wave length and greater penetrating power. About 62 mm. of aluminium is necessary to reduce the rays to one half, and about 50 per cent. are absorbed by 7.6 mm. of muscle.

During the process of decomposition of radium all the three types of emanations are not produced at the same time, but if contained in a sealed tube, the radium soon arrives at an equilibrium so that the decomposition products are uniform as happens when the metal is contained in platinum needles. When radium exists in a natural state, the gas radon is being constantly given off. In the formation of natural spas containing radio-active substances, water percolating through radium-bearing strata comes in contact with this gas radon which is thereby carried away in solution, and to this the curative property of the water is due. But as radon is constantly decaying it is very likely that most of the spring waters lose their radio-activity on keeping.

Units of radium. The common unit of radio-activity is the *curie*, that is, the amount of radon (radium emanation) which is in equilibrium with 1 gm. of radium. This unit being rather too large for practical purposes, the unit used is one-thousandth of this, that is, *one millicurie*, which corresponds to the emanation of a mgm. of radium; the emanation from 0.001 mgm. corresponds to a *microcurie*. 'Mache' unit is approximately 1/2,700 of a microcurie, but this standard has now been discarded.

Pharmaceutical action. The action of radium and radio-active metals is due to the three varieties of rays that they emanate. The softer alpha rays are less penetrating than the hard beta and gamma rays, but they have more intense local action. On protozoa, the alpha rays produce a

rapid lethal effect; the beta and gamma rays have a marked effect upon the developing cells and cells in active state of division; sublethal doses of the latter stimulate all forms of growth.

The action of radium emanations on the skin resembles that of the x-rays. They produce dermatitis after repeated exposure. The alpha rays, which are more superficial, produce more marked effect. This consists of rubefaction and pigmentation of the affected area which pass on to vesication and loss of hair after several days. The blisters may rupture exposing a raw area progressing ultimately to indolent ulceration; when the corium is destroyed the ulcer is deep-seated and the epithelium of the skin invades the underlying tissues producing malignant changes.

The effect on the nervous system is quite characteristic. Mice exposed to large amounts of radium emanations show the following train of symptoms:—forced movements, convulsions, paralysis of extremities, ataxia, paralysis of sphincter control and trophic disturbances. Autopsy shows intense congestion of the spinal cord and brain and degenerative changes in the nerve cells. In man, over-exposure has produced general weakness, vomiting, coma and asthenia and even death.

The germ cells in the ovary and the testis are rapidly destroyed by exposure to radium. *In vitro* the spermatozoa of guinea pig lose their motility, the ovum is also affected; but the interstitial cells remain unaffected. Continued exposure in women may lead to the atrophy of the ovary and menopause.

The gamma rays have a profound effect on the lymphoid tissues; the spleen, lymphatic glands, thymus and Peyer's patches in the intestine show atrophic changes after exposure. Brill and Zehner (1912) found that repeated injections of radium salts increased the number of red cells, this effect persisting for several weeks. The rise in hæmoglobin percentage was not marked. The leucocytes were increased with small doses but diminished by large doses. The following table from Helber and Linser (1905) shows the effect of exposure of rabbit's blood to x-rays.

	Before exposure	After exposure
Red blood cells	7,00,000 per c.mm.	4,50,000 per c.mm
Hæmoglobin	80 per cent.	55 per cent.
Leucocytes	6,500 per c.mm.	1,400 per c.mm
Lymphocytes	2,000 per c.mm.	84 per c.mm
Polymorphonuclears ...	4,000 per c.mm.	500 per c.mm

The coagulability of the blood is said to be markedly increased, *in vitro* the red corpuscles of the guinea pig and sheep are hæmolyse. The capillaries and the endothelium of the blood vessels seem to be specially liable to injury; after irradiation, skin vessels are dilated, there is

diapedesis of leucocytes and later, swelling and extravasation occurs; the blood pressure is said to be lowered.

Fate of radium in therapeutic doses. When soluble radium salts are taken by the mouth or given by injection they are absorbed rapidly, permeate through the tissues freely and are stored in the liver and spleen. Excretion proceeds slowly and occurs mainly by the intestines and some portion by the urine; when given in the form of emanations some breaks up into its degradation product radon and into alpha rays. Radon can be detected in the expired air.

Method of Administration of Radium

Radium emanations. Radium emanation is a gas, given off by the disintegration of the metal. This gas *radon* is being constantly given off from the radium-bearing strata in the earth due to which many natural waters exhibit healing power. In order to obtain the benefit of radio-active waters, away from their source, an apparatus has been devised. It consists of a metal cylinder with a bucket containing the radium salt; this is surrounded by water and left for 24 hours by which time it becomes radio-active. For breathing radio-active gas, air is bubbled through a solution of radium salt; such air gets charged with radon which can then be inhaled.

Radium packs. Radium in packs and pads has been used for a long time in the treatment of rheumatism and similar disorders. They consist of compresses of radio-active substances, sewn in a bag of water-proof material which in its turn is contained in a loose washable cover. These compresses are applied moist and warm to the affected part and left in position for several days.

By mouth. Radium salts, such as radium chloride can be safely given by the mouth in dose of 1/100,000 mgm. several times a day for a number of weeks at a time.

Radium in platinum tubes. Radium when contained in platinum tubes, emits all the three types of rays but platinum cuts off the softer rays allowing only the gamma rays to pass through. This is particularly useful in treating tumours.

The alpha rays have a more intense local action while the beta and gamma rays have less; the gamma rays are specially employed in deep tissues such as tumours. When the action on the skin is desired, as in the treatment of skin diseases, flat applicators are used on which is spread a thin film of salts of radium by which only the alpha rays are allowed to act on the surface of the skin. For purposes of deep therapy it is necessary to cut off the more intense alpha rays, and for this, the rays are filtered by allowing them to pass through some screen of metal. Radium is enclosed in a tube of aluminium, silver or platinum; by this method only the hardest rays are allowed to emanate, the local action is reduced and the rays that

emanate have more lasting and penetrating action on the deeper structures. Aluminium filters are used when treating superficial lesions; silver filters are used for burying tubes and have stronger local action; platinum is employed in the form of tiny needles and embedded in deep structures like rapidly growing tumours. Lead filters have the power of excluding both alpha and beta radiations. The following table from Clark gives the effects of filters on beta and gamma rays from radium.

	Per cent. β -rays transmitted	Per cent. γ -rays transmitted
Lead, 2 mm. ...	0.37	92.8
Platinum, 0.3 mm. ...	2.28	97.2
Silver, 1.0 mm. ...	1.18	95.5
Aluminium, 0.2 mm. ...	63.2	99.8

Therapeutic uses.—Radium is employed in medicine in two ways:—‘Mild radium therapy’ or ‘deep radium therapy.’ Mild radium therapy is intended to mean administration of radium salts in minute doses, or to administer the radium emanations in amounts corresponding to quantities found in natural waters or the external application of radium by means of packs and pads; ‘deep radium therapy’ signifies the treatment of growths and morbid conditions by prolonged exposure to radium.

Mild radium therapy.—Various painful conditions are amenable to mild radium therapy; among these may be classed gout, rheumatism, lumbago, sciatica, varicose veins, neuritis. Even trigeminal neuralgia is said to be favourably influenced by it. Nathan Mutch (1931) states that radium chloride in doses of 1/100,000 mgm. several times a day produces a beneficial effect in arthritis. There may be initial inflammatory reaction, but at the completion of a short course it subsides and is usually followed by beneficial effects; similar results are obtained by the administration of a solution of radon or emanation in water. Mutch (1931) treated series of cases of high blood pressure with small doses of radium. He showed that such doses have a beneficial effect on high blood pressure uncomplicated by kidney disease; in his series of cases pressure reduction varied from 12 to 54 mm. of mercury. Good results have also been reported in angio-neurotic cedema. Leukaemia is treated by exposure to radium or by X-rays. There may be a

temporary decrease in the leucocyte count and also clinical improvement, but the effects are not all permanent. It is generally applied over the spleen or on the bones.

Mild radium therapy is also useful in certain dermatological conditions. The physiological action of mild radium therapy is a stimulation of cell activity arousing all secretory and excretory organs and favouring the elimination of all toxic materials. At the same time the stimulation of the cell activity promotes all metabolism and raises the vitality of the tissues. This explains the beneficial effects of many spas. "Large numbers of people visit the spas for such cures. The radio activity in such cases is due to the presence of radon in the water itself and the gas which accompanies the flow of water from the springs. Accordingly Von Noorden and Falta, in contradistinction to all other forms of electrotherapy, the radio-active substances possess a means of carrying electrical energy into the depths of the body and there subjecting the juices, protoplasm and nuclei of the cells to an immediate bombardment by explosions of electrical atoms. The internal treatment with radioactive waters may, therefore, be designated as internal electrotherapy. In some spas there is also provision for inhaling naturally occurring emanations and this is done by placing the patient in a compartment where such radio active water is flowing.

Intensive radium therapy. Intensive radium therapy has its special field of application in the treatment of new growths. The susceptibility of tissues to radium is dependent on the rate of growth; the rapidly proliferating tissues such as tumours are more susceptible than normal tissues. Malignant tumours are more easily destroyed than benign ones, sarcoma being more susceptible than carcinoma or lymphoid tissues; the ovaries and the testicles and the endothelium of the capillaries are especially susceptible. Nerve and muscle cells are not very sensitive.

The radiosensitivity of a tumour is dependent upon cell structures and the biologic qualities of the parent tissue. Location of a tumour in bone or fat tissue renders it radio-resistant. Active infection interferes with successful irradiation. Successive treatment with inadequate dosage makes the tumour

resistant to radiation. Likewise a tumour becomes radium-fast after a series of treatment with high dosage. Introduction of certain salts (cerium-iodine) into tumour may artificially increase radiosensitivity. Biologic sensibilization has also been practised in some cases; pituitary gland irradiation exerts a beneficial effect in malignant conditions of the female genital tract.

The use of radium in the treatment of tumours is comparatively of recent origin. Special skill and technique are required to decide whether any particular tumour will be amenable to treatment and to select and apply the rays so that maximum therapeutic effects are obtained without any harm to the normal tissues.

For the treatment of superficial growths like rodent ulcers, radium is very effective. In cases of deep-seated tumours, radium may be applied by deep therapy or by implantation of tubes. The softer rays which have intense local action are filtered so that only the hard rays are allowed to pass through; in addition, radium can be applied to the growth from different angles so that any particular site of the tumour does not receive too large a dose.

The implantation of radium in the form of tubes to destroy malignant growths is now widely practised. The tubes are generally made of platinum or lead 1 to 2 mm. thick. These are imbedded in the growth; in general it may be said that 600 milligram-hour (one skin unit dose) destroys most malignant cells. This form of treatment proves effective in early stages; in advanced cases the results are usually discouraging. The most beneficial effects are seen in cancer of the cervix and tongue, cancer of the breast and rectum have also been treated with radium, but so far success has not been uniform.

Dangers of radium and x-rays. The reactions produced by irradiation in the treatment of arthritis are generally mild. These consist of local pain, redness and swelling; the temperature may rise and there may be depression, lassitude and insomnia. These subside in a few days without much trouble. The danger of artificially produced irradiated waters lies in over-dosage. Many preparations sold by quack vendors contain

dosage in excess of the therapeutic limit and this may produce harmful effects. In the treatment of malignant growths, the greatest difficulty lies in giving the proper dosage; sometimes the more actively proliferating cells may be stimulated by the action of radium leading to rapid metastatic changes.

Persons who work with radium show susceptibility to two types of injury with radium, the first due to local action and second the result of systemic absorption. On repeated exposures dermatitis develops which may go on to ulceration and even carcinomatous changes may occur. The rays have got a special destructive effect on the testis and the ovaries and sterility after prolonged exposure, is known. Decrease in the leucocyte count, and destruction of the red blood cells may also occur and in severe cases anæmia and cachexia develop.

Electrocution. With the rapidly increasing use of electricity in industry and for domestic use, electrocution has become quite common. The passage of a strong electric current or the lightning through the body kills the cells by producing electrolysis. The danger of a current passing through the body depends on the voltage of the current, the resistance of the body, and the direction the current takes. The passage of a current through the brain produces immediate unconsciousness. The ordinary alternating current, which alternates about 50 times per second, produces just as much effect as a direct current. Current that alternates very rapidly, *i.e.*, more than 10,000 times per second, is innocuous to the body.

The effects of lightning and high voltage electricity are most marked upon the central nervous system. They are, (a) focal petechial hæmorrhage scattered throughout the brain and especially the medulla. They may also be found in the spinal cord. (b) Chromatolysis of the pyramidal cells, the nerve cells of the medullary nuclei, and of the anterior horn and Purkinjee cells. (c) Curious wide dilatation of the perivascular space. (d) Localised ballooning of the myelin sheath of the peripheral nerves with fragmentation and tortuosity of the axons, breaking down of the sheath of Schwann and infiltration of the epineurium with endothelial cells. These changes do not depend primarily upon the strength of the current, but the duration of the contact and the length of the survival time determine the resultant features.

The main types of injury due to electricity and lightning are (1) *immediate*, including shock, unconsciousness and suspended animation, (2) *secondary*, including burns, gangrene and temporary nervous disorders and (3) *remote effects*, including neurological and ocular complications. The nerve tissues being poorly conductive, the nervous

signs after electrical or lightning accidents are comparatively rare. The cerebral changes after nonfatal lightning or electrical accidents are probably minimal and the minute changes, if any, that occur are of a molecular character and elude the present day power of detection.

CHAPTER VII

DIET AND DIETETICS IN THE TROPICS

The importance that the Indian patient attaches to his diet is not fully appreciated by Western practitioners. The Hakims and Kavirajes lay great stress on the subject of diet. In Susruta, the well-known book on Hindu medicine, it is said, "The physician that does not know the principles of dietetics cannot cure disease." This idea is ingrained in the minds of Indian patients and unless proper attention is paid to this aspect, patients are not convinced about the utility of a particular line of treatment. It is surprising, however, how few physicians practising Western medicine pay any special attention to this important subject. We have, therefore, thought it necessary to give a chapter on this important subject.

Food and its constituents. Food is essential for the maintenance of the body processes. The human body can be compared to a machine, the fuel for which is supplied by the food that we take every day. Food provides the materials for growth and repair of the fabric of the body. It supplies materials which can be oxidised in the body, with the result that the energy set free by oxidation may be used in performing work and in producing heat. It also supplies the body with substances (catalysts, food hormones, vitamins) which though present in almost inconceivably minute amounts, control body function. Food, therefore, is responsible for the conservation of the material of the body, the maintenance of its output of energy and for the regulation of its functions.

On chemical analysis, all foods resolve themselves into the following proximate principles usually known as the 'nutritive constituents.'

1. Proteins, *e.g.*, albumin, myosin, gluten, legumin, gelatin.
2. Carbohydrates, *e.g.*, sugar, starch, dextrin, glycogen, cellalose.
3. Fats, *e.g.*, suet, lard, olive oil, butter, fat.
4. Mineral matters, *e.g.*, common salts and compounds of calcium, iron, iodine, potassium, magnesium.

5. Extractives and flavouring materials.
6. Vitamins.
7. Water.

The various functions of food are fulfilled by the different groups in different measure. The first function, that of building up and repairing the tissues, can be fulfilled by the proteins, the mineral matter and the water. It is true, of course, that glucose, one of the carbohydrates, enters into the construction material of all nuclei, of the mucin of mucous cells and of cartilage; while substances like lecithin with a large portion of their molecules consisting of fatty acid derived from fat, appear in every cell in the body. These substances, however, are almost incidental to the structure of the body which in the main consists of protein, of mineral matter and of water. None of these is sufficient by itself. The second function, that of serving as a source of energy, is mainly fulfilled by the fats and carbohydrates, though we have to recognise that a fair proportion (10-15 per cent.) of the energy output of the body may be derived from the oxidation of the proteins. The third function, that of regulating the processes of the body, is fulfilled by mineral matter and by the vitamins. It is known that muscles (*c.g.*, heart muscle) will not contract in the absence of carefully adjusted amounts of mineral matter. Bone and teeth are irregularly and incompletely formed if in addition to the essential calcium and phosphorus in organic or inorganic combination, there be little or none of the calcifying vitamin, vitamin D, in the food. Many other of the processes of the body depend upon the supply in the food, of minute amounts of mineral matter and vitamins.

The relative value of foods. Physiological opinion has undergone considerable changes during the last century with regard to the relative values of proteins, carbohydrates and fats. Liebig thought that proteins were the chief producers of muscular energy while carbohydrates and fats merely acted as a fuel and maintained the body temperature. This view can no longer be maintained. It is largely a matter of indifference to the cells of the body whether they draw their supplies of

energy from protein, fat or carbohydrate although they can get it more readily from protein and carbohydrate than from fat. The maintenance of body temperature is a natural outcome of the metabolic activities of the cell and will be carried on as long as the cells are alive, irrespective of the nature of the food supplied. Tissue repair, however, is a much more important process than heat production and cannot be maintained without the presence in the food of protein, mineral matters and water. The proteins present should be complete proteins, *i.e.*, contain within them all the essential amino-acids; incomplete proteins such as gelatin cannot by themselves take the place of complete proteins in the diet.

The functions and the parts played by the different proximate principles can, therefore, be stated in tabular form as follows—(Hutchison and Mattram):—

Tissue formers and re- pairers.	Work and heat pro- ducers.	Regulators.
Complete proteins.		
Incomplete protein in the presence of complete pro- teins.	Complete and incom- plete proteins.	Mineral matter.
Mineral matters.	Fats.	Vitamins.
Water.	Carbohydrates.	

It will be observed that the proteins appear in two categories out of three. They are thus of immense importance in the diet. A diet may be predominantly protein and yet life may be maintained thereon. Without protein, life is impossible as the daily wear and tear of tissue protein must be made good.

Determination of the merit of foodstuffs. From the point of view of physicians, a knowledge of the composition and the nutritive values of foodstuffs in common use is of prime importance, as without it, he will not be able to advise his patients as to the nature of the diet they should adopt. There are methods by which one can judge the relative merits of these food materials.

1. **Chemical analysis.** It can tell us how much protein, fat and carbohydrate are contained in hundred grammes of the

food and from this we can form an idea of the value of a particular food as a source of building material or energy.

2. **Physical test.** The amount of heat which a food yields on complete combustion may be taken as a measure of its value as a source of energy to the body. The unit of heat production is expressed in *calorie* which is the amount of heat required to raise the temperature of 1 gramme of water through 1°C . This is the small calorie. For convenience in measuring the amount of heat of foodstuffs, the large or kilo-calorie is used, i.e., the amount of heat required to raise 1 kilogramme (or 1 litre) of water 1°C . (or 1 pound of water 4°F). The determination of the caloric value of a food, therefore, gives an indication as to its value as a source of energy. The heat values of 1 gramme each ($15\frac{1}{2}$ grains) of protein, carbohydrate and fat are

Fat	...	9.3	Calories.
Carbohydrate	...	4.1	Calories.
Protein	...	4.1	Calories.

It will be seen that the caloric value of fat is nearly twice that of protein and carbohydrate. The caloric value of a food, therefore, is greatly affected by its fat content.

3. **Physiological test.** It is not enough that food should contain a considerable proportion of protein, carbohydrate and fat and should be capable of yielding energy on oxidation. It must be of such a nature that it is easily digested in the alimentary tract and absorbed more or less completely into the blood. There are many substances, e.g., saw-dust, agar, hoof parings which are complete foods so far as their chemical analysis and physical properties of heat production are concerned but which nevertheless are not digestible and cannot serve any useful purpose to the body mechanism. In giving opinion on the qualities of a particular food, therefore, several factors have to be taken into consideration.

(i) *The digestibility of foods.* By digestibility, the biochemist means foods which are rapidly disintegrated in the body under the influence of ferments.

(ii) *The satiety value or satisfying power of foods.* This is a physiologico-psychological quality in which foods differ from one

another and is a property which cannot be properly explained. Several factors are at work in giving satiety value to a food and of these the duration of stay of a food in the stomach and the stimulation of the gastric juice are probably important. Fatty foods like milk, butter, eggs, etc., have a high satiety value while 'lean' fish, bread and green vegetables have a low one.

(iii) *Absorbability.* Absorbability of the different constituents of various foods is another important factor in dietetics. Of the three chief nutritive constituents, the proteins are the best and most completely absorbed. Animal proteins (milk, eggs, meat) are much better absorbed and the nitrogen loss is much less than in the case of the vegetable proteins (carrots, potatoes, peas, etc.). Compared with the proteins, fat is apparently very incompletely absorbed. This is probably due to the fact that a fat which is fluid at the body temperature is more easily absorbed into the blood than one which remains more or less solid. The carbohydrates are more completely absorbed than any other nutritive constituent of the food. Sugar probably never fails to enter the blood to the last grain and even starch only reappears in the faeces when taken in a form specially difficult of absorption, e.g., in green vegetables. Hence foods which consist mainly of carbohydrates, such as rice, leave on the whole, less solid residue in the intestine than any other.

A number of experiments have been made by the U.S. Dept. of Agriculture in order to ascertain the degree to which different constituents of various foods are absorbed into the blood. The results are shown in the following table:—

Kind of food	Protein per cent.	Carbohy- drates per cent.	Fat per cent.	Availability of energy per cent.
Meat and fish ...	97	—	95	87
Eggs ...	97	98	95	89
Dairy products ..	97	98	95	98
Total animal foods of mixed diet ...	97	98	95	89
Cereals ...	85	98	90	91
Legumes, dried	78	90	97	88
Sugars and starches ...	—	98	—	98
Vegetables ...	88	95	90	91
Fruits ...	85	90	90	88
Total vegetable foods of mixed diet ...	84	97	—	92
Total food ...	92	97	95	91

(iv) *Roughage*. Though the absorbability is an important guiding principle in the choice of foodstuffs, it is not always an advantage to prescribe a diet which is completely absorbed and does not leave any residue. To ensure the proper action of the bowels, the intestines apparently seem to require a definite amount of ballast or roughage as we now popularly term it. This is particularly true of herbivorous animals which, if fed upon a diet which leaves little or no residue, suffer from affections of the intestines which may prove fatal, whereas such effects can be avoided by adding to the food any material which leaves behind an unabsorbed residue. That this is universally true of man, whose intestine is shorter in proportion and whose food is not strictly vegetable, has been very largely accepted by modern scientists.

(v) *Biological value*. The term biological value is applied to proteins only and its importance in dietetics has only been recently appreciated. By biological value is meant that property of proteins by which they can replace the wear and tear of the body. Thus when it is said that the proteins of milk have a high biological value or those of wheat have a low biological value, it is meant that milk proteins can supply the requisite material for growth at a lower figure for intake than can those of wheat. Proteins of poor biological value have, therefore, to be supplied in larger amounts to counteract the body catabolism than proteins of higher biological value. The biological value of proteins has been expressed in figures. If 100 parts of body protein can be replaced by 100 parts of a food protein then that food is said to have a value of 100. If however 100 parts of it replace only 60 parts of body protein, then it is said to have a value of 60 and so on.

In ordinary dietetics we usually deal with proteins of mixed sources and the quantity consumed is usually sufficient to meet the tissue waste and, therefore, the question of 'biological value' of special proteins does not arise. In the prescription of invalid dietary and under circumstances where life has to be maintained with the minimum quota of protein, the selection of the proper proteins becomes very important. If a protein lacks in the amino acids (lysine, arginine, tryptophane, tyrosine), which are essential to the manufacture of human protein, that protein is absolutely useless to the body economy. For example, gelatin has no tryptophane, no cysteine and very little tyrosine in its composition. Zein, a protein derived from maize, is devoid of lysine and tryptophane. On the whole it has been found out that animal proteins have good supplies of the amino acids in their molecules suitable to the body mechanism while vegetable proteins have considerably less. It, therefore, follows that in

nutrition, animal proteins are more valuable than vegetable proteins. Further, it has been noted that proteins of high biological value raise the biological values of other poorer proteins when taken with them. The function of the cheese, eggs, fish, meat and milk proteins which we take in our diet is to render the vegetable proteins of wheat and other cereals and the pulses of greater value in nutrition than they otherwise would be.

Amount of food required in health. I. *Protein, carbohydrate and fat*:—A good deal of work has been done by physiologists to determine the optimum quantities of the three proximate principles of food, the proteins, carbohydrates and fats, required by human beings for the maintenance of health and efficiency. No definite agreement applicable to the human race as a whole has yet been reached. The body remarkably adapts itself to changes in diet and it will be wrong to apply any hard and fast rule as to what the relations of protein fat and carbohydrate should be. As proteins supply the building material to the body and as a healthy man is always doing a moderate amount of muscular work, the protein quota in food should always be considerably above the loss sustained daily, if a proper balance and growth of the body is to be maintained. It has been assumed, as a result of a large number of observations, that the protein in the diet of an average man should not fall below 80 grammes a day and should contain sufficient quantities of good protein (*i.e.*, of animal origin) to supply 5 per cent. of the total 'calories.'

The carbohydrates and fats in the diet supply the energy required by the body. As far as the demand of the cells for energy is concerned, it is a matter of indifference how much of the total energy required is obtained in each of these forms. To the digestive organs, however, it is by no means a matter of indifference. If all the energy not provided from protein, were to be obtained from carbohydrate, it would mean that a large bulk of food must be consumed, which would not only overload the stomach and intestines but would also be prone to undergo fermentation. If, on the other hand, fat be adopted as the exclusive source of energy, the limits of fat absorption would be overstepped and nausea and diarrhoea produced. The absorbed fat

may cease to be normally metabolised, giving rise to ketosis. Exclusive fat or carbohydrate food, therefore, is not good for the system, though theoretically the required amount of energy can be easily supplied by any one of them individually (much more easily by fats as they have a higher caloric value). The proportion of fat to carbohydrate may, however, vary within a wide range depending upon environment, habit, etc. Thus the Eskimo takes twice as much fat compared with carbohydrate because his environment does not produce plant products; the Indian takes much more carbohydrate than fat because cereals and other articles rich in carbohydrate constituent can be grown easily. It has been estimated that in an optimum diet for persons living in temperate climates, 20 to 35 per cent. of the caloric requirement should be derived from the fats and 55 to 60 per cent. from the carbohydrates.

As a rule, it is appropriate to assume that a man (or woman) who leads a quiet life at home with little exercise requires about 2,500 calories; that if he is engaged in a sedentary occupation, 3,000 calories are required; that if he engages in a moderate amount of exercise or is a labourer doing light work, he can get along on 3,500 calories; and that if he does hard work, 4,000 calories or even more are necessary. Such rough estimates are easy to remember and, while liberal, are sufficiently accurate for most purposes.

Mineral constituents of food. The mineral ingredients of the diet are important building material for the body. This will be evidenced from the fact that the human body contains about 7 lb. of mineral matter.

The chief mineral substances required in the food are sodium, potassium, calcium, magnesium, and iron, along with phosphorus, chlorine, sulphur and traces of silica, fluorine and iodine. Copper must be added to this list, since recent investigations indicate that it is essential for the formation of hæmoglobin. Some of these elements are distributed very unevenly, for 99 per cent. of the calcium and 78 per cent. of the phosphorus is present in the bones, three quarters of the iron is in the red blood corpuscles combined as hæmoglobin and nearly the whole of the iodine is stored in the thyroid gland. Most of the potassium is contained in the cells, whilst most of the sodium is contained in the blood and tissue fluids.

The foodstuffs, proteins, fats and carbohydrates in a pure condition contain only five of the fifteen essential elements, and feeding on a diet free from inorganic substances kills animals within a month and more rapidly than does total starvation. This shows very definitely that the mineral constituents are essential for the maintenance of the fabric of the body.

The mineral constituents cannot supply any heat to the body as they enter the body in a highly oxidised form. They are, however, important in regulating the production of energy in the body. Thus calcium is essential in the production of muscle contraction, whether of the skeletal or the cardiac muscle. Iron is essential for the normal processes of all oxidation and the production of energy by tissue cells, iodine in the production of the secretions of the thyroid gland which govern the body metabolism.

Mineral need of the body. No definite estimate of the quantity of mineral matters required for healthy nutrition can be given. Many of the waste mineral matters of the body are excreted by the intestine, and there is no means of telling what proportion of these has merely escaped absorption, and how much has been excreted from the blood after playing a part in metabolism. A rough estimate of the mineral requirements of the diet in grammes per day is given below (Hutchison and Mattram).

Phosphoric acid	... 3 to 4	Calcium	... 0.4 to 1
Sulphuric acid	... 2 to 3.5	Magnesium	... 0.3 to 0.5
Potassium oxide	... 2 to 3	Chlorine	... 6.0 to 8
Sodium oxide	... 4 to 6	Iron	... 0.015

In the ordinary mixed diet, the amount of mineral matter present is about 20 grammes and, therefore, is usually sufficient for all the needs of the body. Most of the minerals are in a state of organic combination. Thus both calcium and phosphorus are present in organic combination in milk, iron in meat, sulphur in all protein-containing foods and so on. Minerals seem to be utilised in the body much more easily in organic form than in inorganic form, though there is evidence to show that minerals, like calcium and iron, are quite easily absorbed in a purely inorganic form.

Water. It is an essential constituent of all protoplasm and a vitally important factor in the body nutrition. The average water content of the body is about 70 per cent. and this high figure is absolutely necessary to provide the body with a medium in which chemical actions can occur and osmosis and diffusion can effect the necessary transference of chemical compounds through the tissue membranes. It is thus of much greater importance than the ordinary food stuff and is second only to oxygen regarding the proper working of the complex biological

processes inside the animal organism. Since there is a constant loss of water from the body by the kidneys, lungs, sweat glands and bowels, there is a tendency to a greater concentration of chemical compounds in the tissues; but before this can reach a dangerous concentration, the sensation of thirst prompts a replacement of water. This delicate reaction to concentration of the tissue is sufficient to help maintain near its optimum, the balance between water intake and output.

Water may be absorbed into the system through various channels. It is slowly absorbed from the stomach where it also delays the absorption of other substances. It is absorbed readily from the small and large intestines and in these it favours the absorption of substances dissolved in it. In health the absorption mainly takes place from the upper part of the small intestines, the colon only absorbing two-thirds of the water that enters the cæcum. Through the normal intact skin, water is not appreciably absorbed, the outer layer of the mammalian skin may slowly absorb a little quantity, but the passage of significant amounts inwards through the skin does not occur. When ingestion becomes impossible, it is difficult to supply water fast enough through other channels. Rectal administration and parenteral infusion are all inadequate.

The excretion of water occurs mainly by the kidneys, the lungs, the skin and the intestines; and there are many factors which modify the rate of excretion to a considerable extent. Thus if water is taken hot, it favours diaphoresis; if taken in excessive quantity it may lead to diarrhoea and be rapidly eliminated. If it is taken before food, almost an equal amount will be promptly excreted by the kidneys; if it is taken with or soon after food, it may be retained.

The actual rate of turnover of water everyday by the various organs is very interesting. Some of the organs and body fluids such as the salivary glands, stomach, intestinal walls, pancreas, liver and lymph return the water that they drain from the blood. The minimum represented in this way is 3,700 c.cm., a more liberal estimate is 9,800 c.cm. In the case of the kidneys, the colon, the skin with its insensible loss, the sweat glands and in women the mammary glands, the figures for actual total loss of

water from the body range from a minimum of 1,050 c.cm. to the liberal figure 7,800 c.cm. These calculations made by Adolph, permit one to estimate the total daily water turnover at something between 4,700 and 17,600 c.cm., representing an actual possibility of more than four gallons.

The body receives water from various sources—ingested fluids, water contained in solid foods and water produced from the complex chemical processes of metabolism. Water taken along with meals has beneficial effects upon all the digestive organs, provided, of course, the food is well masticated. It aids the digestive action of the saliva, and helps the flow of the gastric as well as the pancreatic juice. It secures better absorption of food, and lessens the putrefactive process of the large intestine.

It would be of special interest in this connection to go into the quantity of water taken daily by the people of the tropics. The various climatic influences demand a more liberal intake of water owing to a comparatively high loss of water from the body due to constant and profuse perspiration.

Saderstrom and DuBois give the data regarding the intake and output of water in the daily life of an average normal individual.

Water intake:—

Drinking water	300 gm.
Water in coffee, milk, soup, etc.	.	..	580 gm.
Water in solid food	720 gm.
Water from oxidation of 100 gm. of protein	41 gm.
Water from oxidation of 110 gm. of fat	118 gm.
Water from oxidation of 244 gm. of carbohydrate	135 gm.
Total			1,894 gm.

Water output:—

By kidneys	750 gm.
By bowels	300 gm.
By skin and respiratory passages	700 gm.
Total			1,750 gm.

Amount retained in the body	144 gm.
Gain in the body-weight	100 gm.

In the tropical climates the figures of both the intake and output are considerably large. Dehydration may result from low water intake or excessive water output, such as may occur in hot climates. Sensation of thirst normally indicates dehydration first, but under certain pathological conditions it may proceed to a dangerous degree before it can be detected. The superficial signs of lack of water are dryness of skin, shrinkage of subcutaneous tissue and diminution in the quantity of urine. In order to find out whether there is adequate supply of water to the body and proper retention, measurement of the body weight is a reliable guiding factor. Most physiologists will agree, however, that all measurements of the state of body with respect to water must be relatively empirical until the mechanism of regulation is better understood.

Dietetic sources of the mineral constituents:—

Calcium. Milk and eggs are the commonest sources of calcium, milk containing 1.5 gm. of lime in every litre. Cheese is very rich in calcium but is not largely consumed in India and probably not in other tropical countries. Foods poor in calcium are meat, fish, bread, fruits and potatoes.

An infant requires about 0.3 gm. (5 grains) of lime daily. The adult, owing to cessation of growth of the bones, requires relatively less (0.4 to 1 gramme). During pregnancy the calcium need of the mother is high for it has been shown that in the last 3 months of pregnancy the foetus requires about 0.3 gm. of calcium a day. The importance of milk and eggs as foods for growing children and during pregnancy and lactation will be apparent from these facts.

Magnesium. Magnesium is usually present in foods in the same proportion as calcium. Milk also contains magnesium and meat more magnesium than calcium.

Iron. Iron is usually present in food in an organic form. It is mainly excreted in the faeces, and hence a definite estimate of the daily amount required by the body is not possible. A normal diet contains about 20 mgm. or more of iron and this quantity is sufficient to meet all physiological demands.

The amount of iron in different foods varies widely. For example, the following quantities of iron in milligrammes per 10 grammes are contained in certain common foods.

Green vegetables	20 to 40
Peas, dried	5.7
Milk	0.2
Beef and eggs	3.0
Rice, polished	0.9

From the results available, it may be concluded that red meats like mutton and beef, and yolk of eggs are very rich in iron, as also vegetable foods like rice, potatoes, spinach, wheat. As regards an ordinary mixed diet, it may be said that the amount of iron which it contains is roughly proportional to its richness in protein, for these two constituents tend to run parallel to each other.

An abundant supply of this metal is of special importance to growing children and to women during pregnancy. The new born infant starts life with a fairly rich store of iron from the mother, and as long as its sole food is milk, it lives on an iron-poor diet.

Sodium and potassium. Sodium is obtainable from the animal group of foods whereas potassium is contained chiefly in the vegetable group. Sodium is absorbed in the form of sodium chloride and, as is well known, this is consumed to a much greater extent than is ever required by the body. The minimum requirement of these salts is from 1–2 gm. per diem but an ordinary mixed diet contains 3 or 4 times this amount and hence deficiency in these salts is not likely to occur.

Phosphorus. Phosphorus enters into the composition of all cell nuclei and it is abundantly present in the bones and in the central nervous system. Wherever growth is going on rapidly a large supply of phosphorus will be required in the food, otherwise development will be seriously impaired. The phosphorus contained in foods is for the most part present in an organic form, part in inorganic form as phosphates of the alkalis or alkaline earths. There is reason to believe that the organic forms are more valuable for contributing to the growth and repair of the tissues; nucleoproteins (liver, kidney, sweetbread), phospho-proteins (milk, cheese, yolk of egg), lecithin (yolk of egg), and other phosphatids and phytin (hexaphosphoric ester of inositol and is found in bran, leguminous seeds and tubers) are all rich sources of organic phosphorus. Fresh vegetables are also good sources of phosphorus.

Sulphur is present in organic combination chiefly in proteins.

Chlorine is ingested almost entirely in the form of sodium chloride.

Iodine is present in small quantities in fresh water plants, water and land plants. The amount required in the diet daily is estimated to be about 45 microgrammes for an adult and 150 microgrammes for a child.

Fluorine and **silica** are present in the body in small quantities chiefly in the teeth and bones. Vegetable foods and especially the cereals, are the most abundant available sources.

A satisfactory diet. A healthy diet, therefore, must contain suitable quantities of:

- (a) Proteins which should be digestible and absorbable and which should have a positive biological value.
- (b) Carbohydrates.
- (c) Fats.

- (d) Mineral constituents including salts, iodine, etc.
- (e) Vitamins
- (f) Water.
- (g) A sufficient roughage.

The diet must also be free from poisonous substances. Certain individuals are particularly sensitive to certain articles of diet and these should be particularly avoided to avert the unpleasant and sometimes dangerous anaphylactic symptoms.

Taking a broad view, one can safely regard a diet as being suitable when large groups of human beings who have lived on it for generations, are healthy and long-lived. The Sikhs of the Punjab attain to perfect physical development on a diet which is quite different from that which is adopted by Europeans. There is a school of physiologists who think that people who are predominantly vegetarians are likely to be more under-developed and short-lived than those who eat considerable quantities of meat. Practical experience of Asiatic races, who are mainly vegetarians, however, does not bear out the contention of these physiologists, as some of these races are just as healthy and long lived as the people of the West who take much larger quantities of animal food. It must not be forgotten that the so-called 'vegetarians' are not truly speaking vegetarians as they usually take milk, which is a product of animal origin. The relative merits of vegetable and meat diet have been set forth by different schools of thought and it will not serve any useful purpose to enter into a detailed description of the points which have been raised in this connection. Whatever may prove in the end to be the best for an ordinary adult, who has great powers of adaptability, there can be no doubt that in the case of children, adolescents and pregnant women, it is far safer to adopt a high protein standard than a low one. No risk must be run of providing too little building material for the growing organism.

THE INDIAN DIETARY

It will be interesting in this connection to consider the dietary of Indians and to see how far this diet comes up to the satisfactory standard. The importance that the Indian ryot attaches to his diet is hardly realised by Western practitioners. It is not uncommon to find a practitioner writing up prescriptions for medicines without any directions as to the nature of the diet his patient should take. The patients often remain dissatisfied in this respect and may lose faith in the physician.

The Indian diet has largely been founded on economic principles but also partly on the long experience of climate.

on social customs, etc., and is now a sound working principle based on a fight against the poor nature of the soil, and the paucity of rains. Two meals are eaten during the day, the morning meal generally consisting of rice and *dal* (pulses) or unleavened bread and curdled milk; the next meal consists of rice with *dal* or vegetables, or unleavened bread with vegetables or meat curry. In villages, the ryot often drinks diluted milk, or curds. In towns during the hot weather some savoury food is taken during the afternoon. Indians are very partial to fruit and in Northern India fruit is eaten before or between these meals. Meat is rarely taken more than twice a week but amongst Brahmins, Buddhists and Jains, meat is not eaten in any form. The nitrogenous portion of the diet is largely made up by milk and *dals* or pulses. We will now discuss these diets in some detail and try to show how far these items of diet supply the necessary proximate principles.

The carbohydrates. The staple food of the people of India is rice. According to the report of the Famine Commission, out of 191 millions people in the country, nearly 68 millions are rice eaters. In the Punjab, U. P., and Oudh, in Behar, the northern parts of the Central Provinces, and in Gujrat (Kathiawar) the poorer classes live on the millets grown in the rains, and on barley and gram; the richer classes eat principally wheat or rice. In Bengal proper, Orissa, and the eastern portion of Central India, rice is the principal food. In the South, in Bombay and the northern parts of Madras, the two varieties of large millets (*jowar* and *bajara*) form the principal food. In Mysore the ordinary food is the small variety *ragi* but rice and wheat are also taken. Baluchistan, the North-Western Frontier Province and in the higher Himalayas a good deal of maize flour is also eaten along with a certain amount of rice.

The carbohydrate food of the Indians, therefore, can be divided into two types:—

(A) Rice—in the rice-growing areas of Bengal, Madras, Southern India and in sub-montane areas of Nepal, Kashmir, and British India.

(B) Flour—as unleavened cakes (*chapatties*). The bread is made from wheat in the Punjab, millets over Central and Southern India and from maize in the N.W.F. Province, and Bihar.

Sugary foods. Sugar is obtained in India from the sugar-cane and to a small extent from various palms, e.g., the date. Coarse sugar (*jaggery* or *gur*) is largely used by the poor classes whereas all sorts

of refined sugars (e.g., *chini*, *misri*) are taken by the richer sections of the population. The Indians are particularly fond of sweet things, and if they can afford it, will consume a considerable amount of sugar during the day.

The variety of sweets eaten are enormous and consist of mixtures of sugar with different preparations of milk, curds, rice, *sufi*, flour, cocoanut. Milk is often sweetened with sugar before taking.

The proteins. (a) *Milk and Milk derivatives.* Milk is the most popular protein consumed in India. As a matter of fact cow's milk is the staple food of the ryot in most of the rural districts of India. In towns, most of the milk sold is a mixture of cow's and buffalo's milk well diluted with water. Cow's milk is considered to be strength building, fattening and beneficial in gastric conditions. Buffalo's milk, goat's milk, etc., are also used in different parts of India.

Dahi or curdled milk is one of the most important milk derivatives. It is nothing but ordinary milk which has been allowed to undergo lactic acid fermentation and coagulates into a creamy white gelatinous mass like junket and has a pleasant acid taste. Curdled milk is better borne by the stomach as it has been already coagulated and its thick consistency makes it possible to be broken up by mastication. Its acid taste makes it more refreshing than milk and when diluted it makes a delicious cool drink in the hot weather. Metchnikoff's view of introducing into the alimentary canal bacteria that will inhibit the proteolytic action of the organism of putrefaction by virtue of the lactic acid produced by them, seems to have some support by this universal custom of taking curdled milk. *Potcheese (chhana)* is made by coagulating milk by citric acid, i.e., the juice of the lemons and removing the whey. It must be used fresh as it deteriorates very quickly. Whey (*ghol*) is a greenish yellow coloured liquid with a sweet acid taste. Whey contains lactose and lactalbumin and is devoid of albuminoids so that it is easily assimilated. Butter-milk is the liquid that is obtained after the milk has fermented and the fat has been churned off as butter. It is called *chachh* (U.P.) or *lassi* (Punjab) and is largely drunk in Northern India. Being fat free, it should be useful in hepatitis, jaundice and sprue.

(b) *Meat.* Meat is undoubtedly the most assimilable form of protein in the food. The religious practices and social customs existing in India are sometimes great obstacles to meat eating. Thus the Brahmins, Jains and Buddhists are prevented from eating meat by their religion. Generally speaking, meat is used sparingly in India. Beef is used only by the Mohammedans and foreigners in India; mutton is more commonly used by the Hindus. The meats of the domestic fowls and wild game birds are also sparingly used. The Hindus in some parts abstain from taking the meat of domestic fowls, but are allowed to eat game.

(c) *Fishes*. There are numerous species found in the Indian rivers; these vary in quality; some are of fine flavour (*Hilsa*, *Mrigal*, *Katla* and other fat fish) while others are poorer in quality (*Koi*, *Singhee*, and other lean fish). Fish is an important article of food in Bengal where very little meat is taken. Sea fish is taken by certain sections of the population living along the coasts.

(d) *The 'pulses' or 'dals'*. The pulses largely supply the nitrogenous constituent of the diet of Indians. Various kinds of pulses are grown all over India and are available at a cheap price. The dals may be taken in various ways, many of them are cooked in the green unripe state as a vegetable. When dried and ripe, the pulses may be cooked as a *puree* with the addition of some ghee. The pulses contain larger quantities of proteins and in many cases make up for the deficiency in foods such as rice.

Fats. *Ghee*. Clarified butter or ghee is the commonest fatty substance taken in this country. Butter is made from milk-fat obtained by churning which mechanically ruptures the albuminoid envelopes surrounding the fat droplets and allows them to come to the surface. This butter is clarified by heat and is then known as ghee. Ghee is used by all classes of people who can afford it, in the preparation of vegetables, curries, etc., and enters into the composition of many of their sweets and pastries.

Sesame oil. The oil from the seeds of *Sesamum indicum* (til) is used in some parts. This oil, however, is expensive and is not much used in cookery.

Cocoanut oil is a fixed fatty oil with a specific gravity of 0.892. The bulk of oil is obtained by cold expression from copra. In Southern India especially in Cochin and Travancore, it is used extensively in cooking.

Mustard oil is obtained by pressing the seeds of the mustard (*Sinapis nigra*). It is largely used in Bengal and in other parts for cooking purposes. The oil must be heated at first to destroy the action of the ferment myrosin and to remove the volatile pungent essential oil. *Walnut oil* is largely used in Kashmir for cooking purposes.

For further information regarding the cereals, pulses, edible oils, etc., used in India, see Appendix.

Errors of Diets in the Tropics

Overfeeding. It is perhaps no exaggeration to say that the tendency of civilised people, and especially of the upper classes in civilised society, is to eat more than the necessary minimum. A moderate excess of food is probably harmless, if not actually beneficial. For it is well to have some reserve in the body which can be called upon in cases of emergency. This limit,

however, is frequently overstepped by the well-to-do people in the tropics. The nature of the diet in the tropics is predominantly of vegetable origin and contains plenty of carbohydrates. The general results of habitual or chronic overfeeding with such bulky carbohydrate food are pendulous abdomen and obesity. The sedentary habit of the majority of people further helps in diminishing tissue catabolism and consequent deposition of fat. Obesity is one of the commonest end-results of overfeeding.

Excess of carbohydrate in dietary. An important dietetic error which prevails among the richer sections of the Indian population is the excessive consumption of carbohydrates and sugars. Bengal seems to be the worst offender in this respect and it is not uncommon to find an average man taking sweetmeats in large quantities both with the morning and the evening meals. The rich man who can afford more, usually takes more of these things. This large carbohydrate intake causes a good deal of strain on the digestive organs and hence gastrointestinal disturbances are quite common in the tropics. Considerable strain is put on the internal secretion of the pancreas which is primarily concerned in the metabolism of the carbohydrates. When this carbohydrate intake is carried on for a very long time, obesity and diabetes result. In some of the well-to-do Bengali families of Calcutta it is the rule rather than the exception for the males to have alimentary glycosuria or frank diabetes before reaching the age of fifty years. Though excessive carbohydrate ingestion may not be the only cause of this high incidence of diabetes in the tropics, this factor is certainly one of the most important causative agents. The sedentary habit is also another factor which cannot be ignored.

Protein shortage in the diet. McCay pointed out that the Bengalis and many of the other races in India suffer from nutritional defects which are associated with the unsuitability of their diet; they are undersized, the average weight being only 50 kilogrammes; their capacity for physical work and their resistance to disease are low; even the kidneys, which might be expected to be healthy, are very liable to degenerative changes in the parenchyma, which result from the lack of nitrogen in

the blood. According to McCay, all these defects are due to the shortage of available proteins in the diet of the Bengalis. When excessive quantities of rice are eaten, the absorption of proteins is seriously interfered with, for example, he found that 8.5 gm. of protein were absorbed when 19 oz. of rice were eaten daily, whereas only 6.5 gm. were absorbed when 30 oz. were eaten. It is, therefore, impossible to make up for the low percentage of proteins in rice by eating large quantities. He also found that the vegetable sources of proteins are often unsatisfactory and these proteins are absorbed much more slowly than the animal proteins. The deficiency of protein in the Indian dietary has also been stressed by a large number of Indian workers. As proteins cannot be stored in the body and kept as a reserve supply for times of emergency, it is only proper that the daily protein intake should not fall to a very low level as is the case with many Indian dietaries.

In general, bodily activity is reduced in the tropics and the digestive powers are undoubtedly not so vigorous as in cold climates. The European coming out to Eastern countries cannot easily give up the dietary habits and tendencies of a temperate climate. A high protein diet which is wholesome and perhaps a necessity in cold countries may actually prove injurious in the tropics. Proteins have a high specific dynamic action and a diet which includes proteins in excess is naturally a 'heating diet.' In hot weather, the production of excessive heat inside the body may be not only uncomfortable but may be actually injurious by taxing the peripheral circulation and sweat glands in the necessity of transferring the body heat to the hot humid air.

Further a predominantly protein diet is likely to leave a very imperfect residue as such diet is always better absorbed. In the tropics the general musculature of the body as well as the intestinal muscles are not kept in that tone which is common in the residents of the cold countries and, hence, constipation results. Habitual constipation leads to intestinal stasis and the absorption of toxic end-products of protein cleavage. Gradually the constitution gets undermined, bowel troubles supervene and mental disturbances in the form of neu-

raesthesia, failure of memory, irritability, etc., result. It is also probable that sprue and appendicitis, so commonly seen amongst the Europeans and so markedly absent in the indigenous races of the tropics, have some relation with auto-intoxication from the bowels.

Alcohol. Indulgence in alcohol is another factor which may advantageously be considered under this section. Though alcohol is not an article of food, it is commonly taken as a drink along with food and this is perhaps one of the most important dietetic errors in the tropics. The Europeans suffer most from the alcohol habit though in recent times, a good section of the Indian community also has contracted the habit. The plea usually put forward is that alcohol is necessary for the maintenance of health and that without its stimulating influence, no strenuous work can be carried on satisfactorily. Others consider it a stimulant which is necessary in the tropics after a day's hard work. It is also believed to be a protective from malaria, and bowel and other diseases. These ideas have all been shown to be erroneous. Though one cannot deny to alcohol the right to be regarded as a 'food' in the scientific sense of the term, it cannot be regarded as a food of great importance, for although it is able to replace fat and carbohydrate it cannot be converted into these, while its secondary effects on the nervous and vascular systems counteract, to a large extent, the benefits derived from the production of heat and energy by its oxidation. Many writers have produced evidence to show that it is not favourable to the production of healthy brain work and mental labour. Alcohol has no influence on physical labour and sustained muscular effort as is generally supposed. It may even do harm by paralysing the sense of fatigue which is the natural check on excessive exertion.

On the other hand, whenever the proportion of alcohol circulating in the blood becomes greater than the cells can rapidly deal with, it acts as a protoplasmic poison. The brain cells seem to be peculiarly sensitive to the paralysing action of alcohol, so that the brain is the first to show the effects of an overdose and intoxication results. If this overdosage is kept up for a very long time, the highly organised and delicate brain

cells would naturally become the seat of various degenerative changes. A certain degree of dulling or even paralysis of the moral perceptions has been noticed in chronic alcoholics by many observers. Apart from its bad effects on the brain centres, the presence of undecomposed alcohol leads to a diminution of the chemical energy of the cells which interferes with the ordinary course of metabolism and may result in chronic disease. The metabolism of fat is most likely to be interrupted and hence alcoholism is a common cause of fatty degeneration.

The excretion of undecomposed alcohol through the kidneys may also act as an irritant and bring about changes in structure and ultimately may produce chronic nephritis. It has injurious effects on the gastro-intestinal tract and particularly on the liver. Alcohol also paralyses the blood vessels and thus interferes with dissipation of heat from the body. It renders people liable to heat stroke and alcoholism is one of the prolific causes of this condition in the tropics.

It will thus be seen that alcohol is an unnecessary article of diet in normal health and is not truly beneficial to the system but is actually injurious from the physiological point of view. Alcohol, there is little doubt, is a potent factor in shortening the life and undermining the health of the majority of Europeans in the tropics. Alcohol strongly predisposes to liver abscess, heat stroke and tropical neurasthenia. It makes the habitue a bad subject for surgical operations and lowers the resistance of the tissues to intercurrent infections. Obesity, diabetes and other disorders of metabolism like gout, etc., have all been ascribed to the excessive ingestion of alcohol.

DIET IN DISEASE

Diet plays a very important part in the treatment of disease in the tropics. Diet may be considered in the light of a therapeutic agent and, like all other remedial agents, has a limited place in therapeutics and should not be considered as a panacea for all ailments. Dietetic treatment is specially important in a particular group of disorders and we will confine our attention to these disorders primarily. The

principles of feeding will only be outlined, the detailed regime will naturally have to be laid down by the physicians with special reference to the particular type of requirement.

The prejudices of patients and the superstitious beliefs existing in India sometime make it very difficult for the physicians to prescribe a regular routine of diet according to strict scientific principles. Thus milk is regarded in some parts of India as injurious to those who have got a cough as it is supposed to increase the phlegm. In some places, it is forbidden in cases of diarrhoea. In prescribing diet these prejudices and beliefs have to be attended to. Individual susceptibility to various foods should also be taken into account.

Diet in fever. The pathological conception regarding the production of fever has undergone a radical change within recent times. In the time of Hippocrates and long afterwards, fever was supposed to originate from bad humour and intestinal irritation and hence the principle of diet was either to starve the patient or to allow only such bland non-irritating and harmless articles, *e.g.*, thin barley gruel and old wine which will allay intestinal irritation and thereby diminish the range of the temperature. A revolt against this starvation diet was not, however, late in making itself manifest and a second school of thought promulgated the idea that fevers were asthenic diseases and should be treated with liberal feeding rather than starvation. Though this doctrine has never been adopted *in toto* in practice, it must be admitted, in the light of our present knowledge of the metabolic changes in fever, that the plan of 'feeding fevers' is a much more rational and sound plan than starvation diet. Thus it has been observed on many occasions that the free administration of food does not, as was formerly supposed, tend to raise the temperature of feverish patients. Von Hoesslin found that in cases of typhoid the temperature during the days when food was administered was only from 0.11°C . to 0.3°C . higher than on starvation days. Moreover, the absorption of light articles of diet goes on as perfectly in the febrile as in the non-febrile state. There is, therefore, no reason why a fever patient should not be allowed to have sufficient food.

up to the limit of his digestive capacity which is greatly interfered with during febrile conditions.

From a study of the metabolic changes, the chief dietetic indication in general fevers, therefore, is to supply a large proportion of protein in the diet to counteract the active protein loss. Though this appears quite a simple matter theoretically, it has been observed that it is impossible to bring about a condition of nitrogenous equilibrium in acute fevers. The noxious action of the toxins on the tissue cells renders them incapable of assimilating proteins, so that the administration of protein diet during febrile stages instead of repairing the breakdown, actually does harm by flooding the circulation with protein cleavage products which are toxic to the liver and the kidneys. It is not logical, therefore, to give too much protein ration to fever patients. Carbohydrates and fats are known to be 'fever protein-sparers' under certain circumstances and the tissue breakdown in fever can only be stopped by supplying these in abundance. Then again, fats are not liked by fever patients probably because they are not readily digested. The carbohydrates, therefore, are our mainstay in dieting fever patients.

General scheme of diet. For purposes of dieting it is necessary to secure such a state of affairs as will coax the appetite, create relish for such insipid food as may be allowed and a clear state of the gastro-intestinal tract. A fluid diet is considered the best by common consent. This evades the necessity for chewing which is rendered difficult by the diminution of the salivary secretion and also relieves the thirst and supplies plenty of fluid to the parched tissues. Milk is the simplest, most accessible and most nutritious of fluid foods and should always form the basis of the dietary. Plenty of fluid drinks may also be allowed. Some workers claim that saline-containing beverages are better than ordinary drinks as these may replace the salts which are rapidly excreted from the kidneys during fever. Such a claim, however, has no real value. The kidneys have the power of re-absorbing through the tubules the salts necessary for tissue metabolism and if we assume that the kidneys are in a healthy condition, there is no reason to

think that the mineral constituents of the cells have drained away through them and that replenishing is necessary through the mouth.

A common mistake in tropical countries, particularly in the summer season, is to allow iced drinks. Though there is no evidence to show that these are injurious in any way, they have been frequently observed to give rise to a congestion of the throat and a distension of the stomach. The excessive consumption of aerated beverages is to be avoided, as tending to overdistend the stomach with gas. The water of unripe coconut (*dab*) is a very pleasant drink available in the tropics and may be allowed if the patient cares to have it.

The system requires much less energy to maintain it at a normal level while in rest than when it is carrying on some muscular work. As all the fever patients usually remain in bed, the caloric requirement is also small. It has been estimated that for an adult human being of average weight, nearly 1700 calories are required in the resting condition to keep it in balance. If four pints of milk are consumed in a day, the necessary caloric value is obtained and there is no necessity to worry about the tissue break-down. If, however, this is not taken for some reason or other, the milk should be fortified. The amount of protein in it may be increased by the addition of such preparations as Plasmon or the proportion of fat may be raised by the addition of cream. It is better, for reasons already adduced, to enrich the milk with carbohydrates like glucose, milk-sugar, cereal preparations like arrowroot, oat flour, corn-flour, barley, sago, *sati*, rice-gruel, etc. Fruit juices like that of orange, pomegranate, grapes, pine-apple, pears, apples, jamrook, etc., may also be given in moderate quantities. Sugarcane is a very good thing in India if the patient is not too weak to chew it. It cleanses the mouth and the juice is very refreshing. In addition to these, soups, beef tea, thin pea or *dal* soup or broths, may be allowed in the proportion of about one pint a day but these are better avoided particularly when diarrhoea is present.

Use of alcohol in fevers. Alcohol is undoubtedly of value in febrile states if it is used in moderation and according to

the direction of the physician. Its properties as an indirect stimulant to the heart is too well known to need any special mention and in fevers which are asthenic conditions, a stimulant in any form should be helpful. Alcohol reduces body temperature by dilating the blood vessels of the skin and diminishes tissue waste specially the waste of fat and these properties should mark it out as an agent of great value in fever. It is absorbed immediately and the tissues can use it as a ready source of energy.

Alcohol has been largely used in conditions of failing circulation in fever which are characterised by a quick, weak and irregular pulse. In nervous prostration and sleeplessness also it has been highly spoken of when the digestive powers are very weak, the property of alcohol to spare the tissues can also be utilised. In cases of hyperpyrexia its use has often been attended with very gratifying results.

Diet during pregnancy. Pregnancy is a natural physiological process, and minor ailments associated with it, such as morning sickness, etc., should not be regarded as pathological. The general health of the average pregnant woman, however, in these days, is poor and she is often considered to be an invalid at such times. A large amount of sickness and disability associated with child bearing is due to our lack of knowledge of the relationship of the nutrition of the mother to the normal functioning of her organs. The serious consequences of a deficiency in many essential food substances and with a pregnancy superadded may be greatly reduced by judicious dieting. This problem does not affect the mother alone, the growing foetus also suffers serious results.

The early foetal growth takes place at the expense of the maternal tissue and there is always an extravagant breaking down of it to enable the foetus to get its requirements. At a later stage the foetus derives its nutrition from maternal food. Over and above this, many chemical substances which are essential for its growth are present only in small quantities in maternal organs and they cannot be synthesised by either the mother or the foetus. A liberal supply of these substances (or their effective precursors) must be from the food the mother

takes. Ordinary diets vary widely so far as the energy bearing factors, the proteins, the fats and the carbohydrates are concerned, and yet they may remain compatible with good maternal and foetal health. The trouble arises, when there is unbalanced dietary and a deficiency of factors essential to proper structure, function and even to life of the mother and of the offspring. Among these are calcium, phosphorus, iodine, iron and vitamins A and D. A pregnant and lactating woman has to supply calcium to the foetus from her own store. Calcium and phosphorus of different foods are retained by the body to different extent and the retention is greatly influenced by the presence of vitamin D. Cereals such as oatmeals and cereal embryo which are rich in calcium and phosphorus are anticalcifying and along with them a well-balanced amount of calcium-retaining factor in form of milk and cod-liver oil (which ensures a good supply of vitamin D) should be ingested. Cod-liver oil also supplies vitamin A which increases the resistance to infection.

The significance of supplying iron to the pregnant mother is that the foetus takes away iron from the mother in order to enable it to store iron in the liver to tide over the milk diet period, when it gets a deficient amount of iron. Consequently a failure to supply mother at such a time with sufficient iron will tell upon herself and the child as well. The daily diet should consist of food rich in iron, such as meat, egg-yolk, calf's liver, green vegetables, etc.

Iodine is of importance both to the mother and the offspring. A deficiency of iodine in pregnancy results in cretinism in the offspring and simple goitre or myxoedema may follow numerous pregnancies in a mother. Sea fish or any kind of living matter from the sea and cod-liver oil should be included in the diet.

According to Mellanby "the diet of pregnancy and lactation ought to include the following:

2 pints of milk daily.

1 or 2 substantial servings of green vegetables—cabbage, spinach or lettuce daily.

1 or 2 eggs or egg-yolks daily.

An apple or orange or some fresh fruit daily.

Sea fish twice or more a week.

Cod-liver oil may be taken 2 teaspoonfuls daily.

The rest of the diet can be made up as the expectant mother desires."

Green-Armytage recommends for the Indians, the following diet with the addition of radiostoleum and Parrish's food.

Cereals	.	<i>Dhenki</i> (home-pounded) rice; <i>atta</i> (whole meal flour) and <i>suji</i> .
Vegetables	..	<i>Sak</i> (green leafy vegetables) in all forms except fried. <i>Sabji</i> (green vegetables, etc.), bean, pumpkins, cucumber, brinjal, green peas, squash, cabbage, cauliflower, tomato, etc.
Fruits	...	All, fresh or stewed.
Eggs	..	Ducks or hens in any form except fried.
Fish	...	Mud fish like— <i>kai</i> , <i>magur</i> , <i>singee</i> .
Meat	..	Mutton, chicken, liver, kidney, etc.
Fats	...	Oils, butter, ghee—sparingly.
Milk	...	Fresh goat's or cow's in any form—plain, <i>dahi</i> or <i>ghol</i> . Avoid buffalo's milk.
Sweets	..	Honey, molasses, jam, jelly, marmalade. No pastry, no cakes.
Fluids	...	Water ad lib., cocoanut water, weak tea, coffee, aerated water, home-made lemonade or lime juice.

It is important to avoid any excess in the individual articles of diet as well as in the total intake of food. The idea that a pregnant woman needs large quantities of food is erroneous. Excess of fat in the diet should be avoided not only during the early months when vomiting is a troublesome symptom, but also during the subsequent months of pregnancy. Vomiting is due at least in part, to excessive fat intake which must be limited.

The position regarding the relationship between diet and toxæmias of pregnancy has been summarised by Mellanby. He says, "It is unfortunate that there is no established clinical or experimental evidence that malnutrition is responsible for those toxæmias of pregnancy which include albuminuria, pre-eclamptic toxæmia, and eclampsia itself. In spite of the absence of such evidence I wish to plead that future investigators of these problems will give some attention to this aspect of the case. The hypothesis that such toxæmias are due to the production of toxic substances by the ~~fetus and placenta~~ has not been fruitful. On the other hand,

there is every indication that they are due to abnormal metabolism and, since so many defects in metabolism are now known to be nutritional in origin, the chances that such a factor is the basis of eclamptic conditions are large.

The final teaching based on the foregoing facts is that proper nutrition is essential to healthy childbearing and that the diet should include throughout pregnancy and lactation a sufficiency of what are known as protective foodstuffs. When plenty of these are taken, there is every reason to believe that the rest of the diet will take care of itself."

In abnormal cases, the diet can be dealt with under the following headings:—

1. Constipation—It is often benefited by increasing fluid intake and the amount of fruit and vegetables in the diet. It is better to avoid taking purgatives of drastic griping type. Saline aperients or lubricants might be used with good results, if at all needed.

2. Albuminuria—In pre-eclamptic cases the dieting should be drastic, the solid part of the diet being epsom salts and glucose and the liquid part water. In milder cases, if they respond to a few days' treatment in bed, on a rigid diet, the pregnancy may be allowed to continue; but the diet should be absolutely protein free. Fruits and vegetables can be taken freely, and milk, cooked in any form, is well tolerated.

3. Pyelitis appears about the 20th week and frequently simulate appendicitis. Massive doses of alkalies with a ketogenic diet often help the patient to tide over an attack.

Diet during lactation. During lactation, the regulation of mother's life is of the utmost importance. The diet should be of plain nutritious food. An ordinary well-balanced diet is best for producing a good supply of milk during lactation period. There are no galactagogues known to be of positive value. In cases where milk is poor or deficient in quantity, thick malt extracts, a table-spoonful three times a day may be prescribed. Where the fat is deficient, plenty of butter, cream and olive oil may be added to diet.

Hoobler has found that diets containing milk proteins and animal proteins are better for producing milk than those contain-

ing vegetable proteins. Over-feeding never increases the quantity of milk. Cow's milk protein is the best form to increase the milk production and to protect the mother's tissue. Besides the food factor plenty of rest and daily bath, a daily walk in open air and as much outdoor life as possible are essential. Tea or coffee should be taken in moderation and anything containing vinegar, spices, mustard, or rich and complicated dishes should be avoided.

Diet during infancy and childhood. It is seldom, if ever, necessary to have recourse to any artificial means of nourishing the newly-born infant. It is the baby's birth-right to be nursed by its own mother and breast feeding is always the best for both the mother and the child. It gives the greatest security against intestinal disturbances and infection which are the commonest troubles with the new-born. The child is more strong and vigorous as compared to those artificially fed and better adapted to surroundings.

When for some condition or other either with the mother or the child, breast feeding is contraindicated, the baby may be fed artificially. There is, however, no perfect substitute for breast milk. Although the results of careful artificial feeding are satisfactory, the problem is beset with difficulty. When a child is called upon to digest food of a different form and build up the body from materials of different quality, he naturally starts at a disadvantage. The younger the child, the greater is the difficulty. Before substituting any form of artificial food for mother's milk, the following points should be considered very carefully.

1. The choice of food.
2. The method of preparations.
3. The amount of food required in twenty-four hours.
4. The size of each feed.
5. The interval between each feed.

Cow's milk, goat's milk and ass's milk may be used for the purpose and of these, the cow's is the most generally used. From a comparison between the composition of cow's milk and that of breast milk it appears that cow's milk contains a large ~~excess~~ of protein and salts but too little sugar; the fat is in

about the same proportion. In order to make it of the same proportion as the human milk, it should be diluted with water and some fat and sugar be added to it. One heaped tablespoonful of sugar of milk and half an ounce of cream, added to half a pint of cow's milk, and made up to a pint with water is, however, a good substitute.

Not all infants, even if normal and healthy, can be fed in the same way. The food should be modified as regards the quantity of each ingredient—fat, sugar and protein, in such a way, as to suit the requirements of the individual child

As regards the amount at each feed, it is customary to begin with 3 ounces; this may be raised to 4 ounces at the end of first month, $4\frac{1}{2}$ during second month and so on. Approximately a child will take 1 to 2 ounces more at a feed for every month of age till 8 or 9 ounces.

Intervals between each feed may be four hours but what is the most essential is the regularity. The child should never be waked up at night for its feeds.

Various patent milk preparations are on the market but these should be avoided whenever possible. None of them are well balanced, all have vitamin deficiency, and many contain excess of fat which gives rise to infantile liver or gastro-enteritis in children.

It is sometimes very useful to add some additional factors to the artificial diet. Cod-liver oil should be started at three or four months in amount of 5 to 20 drops twice daily and continued till the age of eighteen months. Fruit juice should also be added at least two teaspoonfuls daily and gradually increased.

Indications for special modifications. 1. Flatulence and habitual colic are invariably due to over-feeding—the food being given very rapidly, most often at too frequent intervals.

2. Curds in stool—This is generally caused by feeding the baby on an unsuitable mixture or when the digestive power of the child is weak. The difficulty may be remedied by boiling the milk and dilution.

3. Vomiting, loss of appetite, constipation and diarrhoea are other difficulties in artificial feeding and they can always be dealt with by attaining the proportion of all the ingredients.

Feeding of older children. A knowledge of nutrition of a growing child as regards both the amount and kind of food necessary for proper growth and maintenance of health is very essential. The points to be noted in this connection are—

Its constitution, *i.e.*, (a) vitamin, (b) salts, (c) proteins, (d) fats, (e) carbohydrates and (f) water.

The forms in which these elements are to be provided.

The relative proportions of the various elements and the total daily amount of each.

Under modern conditions we are faced with the difficulty of formulating a well-balanced dietary for children.

The ideal diet consists of fresh milk, cream, butter, cheese, curds, eggs, etc.

Cereals	Wholemeal flour, wheat or rye—given in form of bread or cakes.
Vegetables	Green vegetables and tubers.
Fruits	Oranges, apples, plums, bananas, etc.
Sugar	Pure honey.
Meat foods ...	Lamb, chicken, rabbit, calves' liver may be given occasionally.

In the ordinary way the diet is laid down empirically and attention is given to the quality of the food, the quantity being determined in a healthy child by the appetite. The real test of the value of a diet is its clinical results.

The estimated requirement which determines the necessity of a generous supply of food throughout childhood and one relatively in excess of that required for the adult, may be quoted shortly as follows:—45 calories per pound body weight at one year, gradually decreasing to 36 calories per pound at six years and remaining at this figure until puberty.

VITAMINS

The subject of vitamins is new but is rapidly growing. A large amount of literature has been amassed during the last decade and more is coming. A good deal of confusion which once attached itself to the subject has now been cleared up and

vitamins have now earned a lasting place in therapeutics. As with everything new in therapeutics, vitamin preparations are becoming a craze with the medical profession and are being regarded as a panacea for most of the dietary evils of humanity. It is necessary to emphasize that the problems of nutrition must not be viewed from a too 'vitaminic' outlook. Vitamins are certainly important in nutrition and in the maintenance of normal health, but it is only one link in a chain of essential substances requisite for the harmonious regulation of the chemical processes of healthy cellular action. The diet of most of the tropical races is extremely ill-balanced and one-sided; hence it is essential for all students of tropical medicine to have a general knowledge of the value, properties and distribution of these 'accessory food factors.'

Evolution of the knowledge of vitamins. It has long been recognised that the diet must represent not only a certain amount of calories but that it must include certain proximate principles in the form of proteins, carbohydrates, fats, etc. Magendie, before 1820, appears to have been the first to demonstrate the indispensability of protein food. He showed that dogs fed on exclusive diets, such as sugar, olive oil or butter, became emaciated, developed perforating corneal ulcers and died in three to five weeks. It became known quite early that one-sided diets are likely to result in general malnutrition and special diseases such as scurvy, rickets, etc. Early in the eighteenth century, it was recognised that green vegetables or the juice of citrus fruits were the only agents which could cure or prevent scurvy. As early as 1600 A.D., lemon juice was used with success to prevent scurvy in sailors, and in the eighteenth century, Lind definitely showed that scurvy could be prevented by the use of lime juice.

During the latter half of the nineteenth century, beri-beri spread in all rice-eating countries. Takaki of the Japanese Navy thought that the disease was caused by errors in dietary and in 1885, he reformed the naval diet by adding more meat and substituting barley for a part of the rice which had previously been the principal article of food. These changes were very successful and beri-beri practically disappeared from the

Japanese Navy. Eijkman (1890) working in the East Indies found that by feeding fowls on polished rice, a polyneuritis closely resembling beri-beri could be produced. This polyneuritis could be prevented or cured by giving the fowls small quantities of rice-polishings or its extracts.

The existence of two deficiency diseases was thus established by the end of the nineteenth century. Although experience of these deficiency diseases was quite old and although scurvy was recognised as early as the eighteenth century, yet the existence of vitamins was first demonstrated by Sir Gowland Hopkins as recently as 1912. This discovery stimulated an enormous amount of research and by 1918, it was recognised that at least three separate vitamins existed and that the presence of all these in the diet was essential for the maintenance of life.

Vitamins. The works of Hopkins, Funk, Osborne and Mendell and a host of other scientists have shown very clearly that a diet may contain suitable quantities of all the well-recognised constituents, and yet be incapable of maintaining the body in a healthy condition. Vitamins are those remarkable food components, of which minute quantities must be supplied if normal growth is to occur or even if normal health is to be preserved. The classical experiment by which Hopkins established the existence of vitamins was as follows.—He found that eight young male rats when fed on a purely synthetic diet, which was apparently complete with regard to carbohydrates, proteins and salts, did not grow at all. On adding fresh milk to the diet, growth immediately began and proceeded in a normal fashion. When milk was removed, growth stopped. From these effects, Hopkins pointed out that certain 'accessory food factors' are also needed for growth. For some years after the discovery of these substances by Hopkins, there was a tendency to regard them as highly unstable in character and to doubt whether they would ever be isolated or their chemical nature revealed. The outlook has profoundly altered in recent years. To-day, three of the vitamins have been isolated in very nearly the pure condition, and it is generally accepted that all members of the

class are substances of comparatively simple chemical constitution. Funk proposed the name 'vitamine' for these substances, as he thought that chemically they are of the nature of amines. The name 'vitamin' has now come to stay though it is spelt without an 'e.' Some of the American writers have still kept the original spelling, 'vitamine' employed by Funk.

Sources. The 'vitamins' or 'accessory food factors' occur in a great variety of foods, but appear to be formed mainly in plants. They are rather unstable and for the most part are stored in animals only, for short periods. Vitamins are present in most of the natural foods both animal and vegetable; particularly in glandular organs and products, including milk, eggs and liver and in green vegetables and fruits and in the embryo and hulls of cereals. They may also be prepared from yeast. Meats, potatoes, flour, most oils and sugar products are relatively deficient in vitamins.

General results of vitamin deficiency. The effects of vitamin deficiency resemble closely those of starvation. Growing animals, because of their relatively greater need of food, suffer more than adults and proliferating tissues suffer more than those that are stationary. Inadequate supply of the vitamins results in impairment of appetite, nutrition, growth, fertility, general health and of resistance to infective and other unfavourable agencies. Vitamin deficiency is probably also responsible for intestinal paresis and consequent stasis and bacterial fermentation. This observation gains support from the experiments of McCarrison. He found in pigeon and guinea pigs, suffering from experimental vitamin deficiencies that the intestine showed atrophy of the muscular coats, lesions of the neuro-muscular system and impaired digestion and absorption.

It is not always necessary that vitamin deficiency will manifest itself as in cases of frank disease like rickets, beri-beri, pellagra, etc. McCarrison and others have insisted that there are many cases of ill-health which are due to shortage of vitamins in the diet. Diarrhoea and gastro-intestinal complaints of obscure origin and lowered resistance to disease are believed to be associated, in many cases, with vitamin deficiency.

Classification of the vitamins. All the vitamins have not yet been isolated in a pure condition and, hence, it is not possible to offer a dogmatic classification. According to their actions and solubility they may be arranged into a few groups but it is not definitely known whether each group includes one or several substances. The existence of six different vitamins has now been fairly well established, and we will confine our remarks to these better-known factors to the exclusion of those which are still in an experimental stage. These may be classified as follows:—

Fat-soluble vitamins.

A—Anti-infective and anti-ophthalmic vitamin.

D—Anti-rachitic vitamin.

E—Anti-sterility or reproductive vitamin (vitamin X).

Water-soluble vitamins.

B—Anti-neuritic vitamin (vitamin F in U. S. A. terminology).

B₂—Anti-pellagra vitamin or anti-dermatitis vitamin (vitamin G in U. S. A. terminology).

C—Anti-scorbutic vitamin.

There are probably many other substances of this class which are not at present identified. There is, for example, 'bios,' a substance which appears to be essential for the growth of yeasts and bacteria and which bears some close relationship to B₁ and B₂. Before 1918, three vitamins, namely, A, B and C were only recognised. Vitamin A was recognised as a fat-soluble-vitamin, B as water soluble and C as anti-scorbutic. Later, vitamin A was split into A and D, A being anti-infective and anti-ophthalmic and D, anti-rachitic. Within the last few years, the existence of a third fat soluble vitamin E (or vitamin X) called anti-sterility vitamin, has been established. Vitamin B has been split into at least four components, of which two, B₁ or vitamin F and B₂, the so-called 'Pellagra preventive' (PP) or vitamin G, are here considered. There are probably many more similar substances. It is not really surprising that there should be a considerable number of substances which the animal

body requires in small quantities for growth and which it cannot manufacture itself.

Nature and properties of the vitamins. Ten years ago nothing was known regarding the chemical nature of these vitamins. To-day, it is possible to manufacture one of them, for vitamin D can be made by irradiation of ergosterol by ultra-violet light. Ergosterol can be obtained from yeast, and therefore this vitamin can be produced in a nearly pure condition in large quantities. Though we have got much less precise information with respect to the other vitamins, they can now be obtained in very concentrated forms which is a distinct advantage from the point of view of therapeutic administration. Concentrated A can be obtained from liver oils, and the provitamin 'carotene' from the yellow pigment of carrots, concentrates of vitamin B from yeasts and concentrates of vitamin C from orange juice. The medical use of vitamins is, therefore, practicable to-day.

An essential characteristic of some vitamins is that they are readily destructible. In nature, most of them slowly oxidise when food is preserved, unless oxygen is excluded. In most cases they are readily destroyed by alkali in the presence of oxygen or by absorbents (*e.g.*, charcoal) in the presence of oxygen. Hence great care should be taken to preserve them. No chemical tests are known by which most of the vitamins can be estimated quantitatively, and hence biological tests, which take a long time, are essential. There is a reaction by which vitamin A can be recognised but in the case of the other vitamins, biological methods have to be resorted to. Experience has shown that certain animals are highly sensitive to lack of certain vitamins and these animals are utilised in actual practice for purposes of testing and assay.

The quantity of vitamins required to maintain the body in health is probably a small fraction of a milligram a day. This suggests that they are more likely to be needed for the production of the hormones than directly for the general growth and nutrition of body cells.

Effect of cooking. Vitamins A, B, and D are fairly stable to heat and are not destroyed to any great extent in cooking unless alkali is added, as in cooking of vegetables. Eighty per

cent. of vitamin C content of vegetables is destroyed by boiling for an hour. Cooked foods may thus furnish an adequate supply for most of the vitamins except vitamin C.

The preservation of vitamin. Fat soluble vitamins can be kept active for years in solution in fats or in oils, especially if kept hermetically sealed. Tinned meat and butter may, therefore, contain these vitamins in adequate quantities. Vitamin B can be preserved for very long time in dried seeds and is only destroyed by some artificial process. Vitamin C can be preserved with great difficulty. The process of drying and preservation in tins completely destroy this vitamin in vegetables; but the vitamin C of fruits is more stable and can be preserved in the juices of citrus fruits and in tomatoes. Preservation of vitamin in milk is of a great practical importance in the feeding of infants. Pasteurisation and scalding of milk destroys about half the vitamin C content, whereas condensing or drying destroy only variable amount. Spray drying destroys the greater part of vitamin C; even by the best methods of drying about one half of the content of vitamin C can be retained.

Fate of the vitamins in the body. Little is known of the fate of the vitamins after ingestion; but they appear to be partly destroyed in the body and partly eliminated in the excrements. There is evidence to show that these substances are liable to be neutralised by the action of certain abnormal ferments or bacterial toxins in the alimentary canal, so that it may be necessary at times to give larger doses than those which ordinarily suffice

FAT SOLUBLE VITAMINS

Vitamin A

Occurrence. This factor is most abundant in animal tissues, particularly in the intracellular fat of liver and glandular organs and, therefore, in butter fat, egg-yolk, fat-fish, fish-roes, fish liver and cod-liver oil. It is also widely distributed in plants, especially in the green leaves. The A vitamin is apparently synthesised only by the chlorophyll of plants in the presence of light. Lower plants without any chlorophyll cannot produce vitamin A. Germinating seeds do not contain it until they have produced green leaves. Animals derive their supply of vitamin A from

the green plants directly or indirectly and store any excess especially in their livers and fatty tissues. The vitamin A content of foodstuffs of animal origin (milk, butter, eggs, etc.), therefore, is governed by the diet of the animal.

The original source of the fat-soluble vitamins in cod-liver oil is the chlorophyll-containing diatoms, which are eaten by plankton organisms and these, in their turn, by the small fishes which form the food of the cod. The fat-soluble vitamin in cod-liver oil have, therefore, passed through a series of animals before being stored in the cod's liver. Similarly the vitamin A in milk is derived from the fresh vegetables in the cow's diet and hence the milk of grass-fed animals is rich in this vitamin, but that of stall-fed animals may contain very little. In nature, vitamin A is always associated with the antirachitic vitamin D.

Carotene (provitamin). The yellow colour of many vegetables, especially carrots, sweet potatoes, yellow corn and certain vegetable oils, is due to a lipoid-soluble substance which has been isolated in a crystalline form by Schertz (1925) and later by von Euler (1928). This substance has been designated as 'carotene' and it has further been identified in animal kingdom, *e.g.*, in fish, hen's eggs, butter, corpus luteum, blood, etc., being derived probably from the food.

Euler showed in 1928 that carotene produced complete protection in animals on a vitamin A deficient diet. This statement was confirmed by Steenbock and his co-workers. The two substances, carotene and vitamin A, generally but not necessarily, occur in the same food-stuffs. Moore (1931) has reported that the feeding of animals with products rich in carotene greatly increased the vitamin A content of their liver fat, materially beyond that of cod-liver oil. It is, therefore, plausible to assume that carotene is biologically related to vitamin A and that carotene is a precursor of vitamin A and is converted into an active form in the body. The weight of modern opinion seems more to lean to the view that carotene is the precursor (the provitamin) inasmuch as it differs from vitamin A in certain physical, chemical and biological characteristics, *e.g.*, solubility, colour, absorption of light in the spectroscope and heat stability. The potency of active carotene approaches that of the vitamin A; 0.05 mg. produces normal growth in a 100 gm. animal which has been deprived of vitamin A. Carotene can be easily obtained and purified and has now been

accepted as an international standard for comparison of the vitamin A content of foods.

Composition and properties. The vitamin A is soluble in oil and fat solvents and also fairly soluble in water. It is less stable than vitamin D, being destroyed by oxidation. By passing oxygen through heated cod-liver oil, McCollum could destroy the A vitamin completely. In butter, the vitamin is confined to the portion of the fat with low melting point and is not destroyed by steam.

Steenbock succeeded in concentrating vitamin A into a fraction of the unsaponifiable lipoids of cod-liver oil. Seel (1930) claimed to have isolated the substance in a pure form which, however, was found to be very unstable. He believed that it is a labile oxidation product of oxycholesterol. Its relation with carotene has already been discussed.

Physiological effects. An adequate supply of vitamin A in the diet is essential for satisfactory growth in childhood and for the maintenance of a normal resistance against infection both in young and in adult life. Its deficiency causes suspended growth, increased susceptibility to infections and in advanced cases 'xerophthalmia.' The first symptoms of this trouble is night-blindness, a disease known for many years and fairly common in war prisoners' camps during the Great War. As the trouble progresses, opaque spots are seen on the sclerotic, then there is conjunctivitis and blepharitis and, if not checked, ulceration of the cornea, leading to blindness. Famine and industrial depression bring the disease to light. The experimental work of Mellanby and Green showed in a striking manner the lowering of the resistance against bacterial infection with a diet deficient in vitamin A. Clinically, this property of vitamin A has been utilised by many workers with very promising results. Lassen's work (1931) on the relation between vitamin deficiency and susceptibility to paratyphoid infection is very significant. In an extensive study he found that a decreased resistance to this type of infection was most noticeably associated with a reduced intake of vitamin A. The results of investigation on the role of vitamins A and D as

prophylactic agents against puerperal sepsis in the outpatient department of the ante-natal clinics of Sheffield are also very striking. Half the patients (out of 550 patients) were given an extra supply of vitamins during the latter week of pregnancy. Of these treated cases only 1.1 per cent. developed the British Medical Association standard of morbidity as compared with 4.7 per cent. in the control groups. Vitamin A deficiency is also supposed to be responsible for gingivitis, pyorrhoea, decay and an increased susceptibility to colds. These are, however, not definitely proved facts.

Deficiency phenomena in animals. 'Young animals respond promptly to vitamin A deficiency by arrested growth and xerophthalmia. In young rats, this may develop in 2 or 3 weeks. The epithelium of the eyeball and eyelids are not the only one to be affected. Animals kept on a diet without vitamin A show lesions of the epithelium of the mouth and throat, of the respiratory apparatus and of the urogenital tract. Von Veersum (1928) has shown that deficiency of vitamin A is one of the causes of stone formation in the kidney and bladder. Deficient bone formation is manifested by delayed dentition and rickets. In adults the results may not be noticeable for several months as they have got large reserves of vitamin A in their body fat. Body weight decreases and the resistance to infection is lowered. Intestinal disturbances occur and intestinal bacteria may invade the blood stream.

Colour (tintometric) test for vitamin A. When arsenic or antimony trichloride is added to an oil containing vitamin A, a blue colour is produced and the intensity of the colour is roughly proportional to the vitamin A content. This test provides a simple and rapid method for the approximate estimation of the vitamin A content of fats and oil and obviates the necessity for the biological test which requires 8-10 weeks. This colour test has not yet been established beyond all doubt as a measure of the vitamin A activity, but all the evidence so far obtained indicates that it is useful. The absorption spectrum of the colour produced in this test has been determined by Rosenheim and Drummond (1925) and confirmed by Wokes (1928). With arsenic trichloride bands at about 587 and 475 μ respectively were obtained. With antimony trichloride, bands at about 614 and 590 μ respectively were obtained.

Vitamin D (Calciferol)

This vitamin is present in cod-liver oil in relatively large quantities and also occurs in fish oils (*e.g.*, salmon, herrings in Western countries; *hilsa*, king fish, etc., in India), animal fats, eggs, and butter; green leaves contain only small quantities. It is now known that vitamin D is produced by the exposure of ergosterol to a special wave band of ultra-violet light. It may be produced artificially by such irradiation of the isolated ergosterol or of many foods and oils which contain ergosterol.

The history of discovery of vitamin D is particularly interesting. In 1922, McCollum, Simons and his co-workers showed that vitamin D is quite distinct from the growth-promoting vitamin A as the former is more resistant. Later work confirmed that 'D' does not protect against xerophthalmia and other manifestations of 'A' deficiency. In 1919, Huldschinsky noted that rickets could be cured by exposure to ultra-violet light and it was soon found that exposure to sunlight also exerted a powerful curative effect on rickets. This suggested that there was some connection between ultra-violet light and the fat-soluble vitamin. Hess and Steenbock (1924) independently and almost simultaneously discovered that antirachitic properties can be conferred on many foods and oils, which are not in themselves antirachitic, by short exposure to ultra-violet rays. Starting with the observation that ordinary cholesterol is rendered antirachitic by such irradiation, several investigators tried to discover what exactly was the molecular change that was brought about on irradiation. This led to the examination of many of the known compounds of cholesterol. After a good deal of experimental observations, it was found that cholesterol itself could not be turned into the antirachitic factor by irradiation but it was some impurity in that product. In 1926, Rosenheim and Windaus showed that the active principle or the provitamin D was indeed a sterol of an unsaturated and labile type, of which ergosterol is the only known representative. Ergosterol itself was found to have the same absorption spectrum as cholesterol which could be activated. The inevitable conclusion, therefore, was that ergosterol is the precursor of vitamin D.

Composition and properties. Ergosterol occurs in all tissues especially in the nervous system, skin and adrenals. It was originally produced from ergot and, therefore, called 'ergosterol' but is now prepared almost exclusively from yeast. It is chemically related to cholesterol but as has already been pointed out, differs from these sterols in its property of being activated by ultra-violet light and acquiring a property of curing rickets. The chemical nature of the change which takes place in the ergosterol following irradiation is not known. Possibly an isomeride of ergosterol is formed. That a good deal of change

occurs in the original molecule is revealed by successive alterations in the spectrum. During the early stages of irradiation of ergosterol, the amount of vitamin D slowly increases but a stage is reached at which formation and destruction go on at the same rate, so that for some hours the amount of vitamin D in a sample of ergosterol remains constant; then a stage comes when all the ergosterol has been converted into vitamin D, most of which has been destroyed. Continued irradiation completes the destruction of vitamin D and the preparation is without antirachitic property. The maximum amount of vitamin D present when a solution is irradiated at room temperature is about 10 per cent.

This work naturally suggested the advisability of irradiating ergosterol with rays of particular wave length only, and not with the whole range which comes from a mercury vapour lamp, some of which obviously have a destructive effect. Vitaglass cuts off the rays below 260 and would, therefore, apparently be useful in letting through the needed rays.

The antirachitic property of activated ergosterol or 'viosterol' is 250,000 times that of cod-liver oil and 0.00002 mg. would protect a rat against experimental rickets. The pure dry viosterol soon loses activity but irradiated foods remain active for at least six months and oily solutions of viosterol appear to retain their full activity indefinitely.

Effects produced by vitamin D. Deficiency of vitamin D in the diet results in deficient and defective formation of teeth and bones. The administration of viosterol cures the defective bone development and all other manifestations of human rickets and that produced in experimental animals by diets deficient in vitamin D. How this bone development is retarded is not known. There is evidence to suggest that one of the primary effects of vitamin D deficiency is to render the gut contents more alkaline than normal and thus to interfere with the absorption of calcium. The improvement after the administration of vitamin D starts with progressive calcification at the epiphyses, and is evidently connected with the proper relation of calcium and phosphate in the blood. Even when the diet contains the proper amounts of calcium and phosphorus which are necessary for bone formation and bone development, lack of vitamin D results in a disturbance of the metabolic balance resulting in defective bone formation. In the growing animal the bones laid down are so deficient in calcium phosphate that they are unable to support weight and bend.

The mechanism of action of vitamin D is unknown. It resembles at least superficially that of the parathyroid hormone but the effect is not exerted solely through this gland since it occurs also after parathyroidectomy, although the doses to be given must be a thousand times more than the ordinary.

Effect of overdosage. Attention has been called, during the past year or two, to the possibility of a disease or a condition caused by overdosage of vitamin D known as *hypervitaminosis*. A single dose, even if large, does not produce permanent ill effects but continued administration results in the depressive symptoms of hypercalcaemia. Loss of appetite, lassitude, drowsiness, pallor, emaciation, etc., are some of the signs noticed in these patients and later calcification of tissues, *e.g.*, arteries may take place. The susceptibility varies somewhat in different individuals but the margin between therapeutic and deleterious dose is a wide one.

Diseases Produced by Vitamin D Deficiency

Rickets. Rickets does not play so great a part in the tropics as in cold countries. According to an estimation by Hess, rickets occurs to the extent of nearly 7.5 per cent. amongst the children of the urban population of the temperate regions. This is certainly not the case in India and other tropical countries but the disease is not altogether unknown. There are some places in Southern and Western India where a mild form of rickets is fairly common among children, who are reared in dark rooms.

It is now definitely known that rickets is caused by deficiency of the antirachitic vitamin. For many years, there was a dispute as to whether rickets was caused by a deficient diet or by bad housing and consequently deficiency of sunlight. Recent experiments have explained the results satisfactorily and have shown that when an animal is exposed to sunlight or to the ultra-violet light from a mercury vapour lamp, a certain amount of vitamin D is synthesised in his skin. Hence rickets can be prevented or cured either by the supply of an adequate amount of vitamin D in the food or by exposure of the subject to ultra-violet light or sunlight. Cod-liver oil, fresh milk

animal fats, butter, etc., contain fairly high percentage of vitamin D and can be used in all such conditions. Irradiated ergosterol or viosterol is a highly concentrated form of vitamin D and can be used when cod-liver oil cannot be tolerated on account of gastro-intestinal disturbances. In tetany and spasmodophilia and during the lactation period, vitamin D is also of great use.

Osteomalacia. This disease is very common among females in some towns and cities in India (Bombay) and Kashmir and also in other countries in which the purdah system prevails. It is entirely unknown among people who lead an outdoor life. There is abundant evidence that the disease is caused by lack of sunlight and antirachitic vitamins. Osteomalacia has frequently been called "adult rickets."

The disease may occur in a very mild form among males but it is essentially a disease of women who are forced to live in purdah in many parts of India. The disease makes its appearance particularly at the time of attainment of puberty and is frequently exaggerated at the time of pregnancy when the foetus takes away much of calcium from the mother's blood. Manifestations of hypocalcaemia become evident in the form of general weakness, pains in the pelvic regions (so-called 'girdle pains') and tetany and spasms of the muscles. In due course, softening and deformity of the bones set in. These cause their most disastrous effects in the pelvic bones—the bony pelvic outlet is shortened and there is great difficulty at the time of parturition.

The administration of vitamin D either through food or as irradiated ergosterol has prevented the progress of the disease; in many cases sunlight and fresh air to stimulate the skin to manufacture vitamin D should also be resorted to. Viosterol is, however, not so specifically active in this disease as it is in rickets.

Dental caries. What is true of bones is true also of teeth. Deficiency of vitamin D in puppies, rats and rabbits, has produced a condition of caries which is very similar to that affecting human teeth. For teeth to be perfectly formed a supply of vitamin D from the inception of calcification till it

is complete, is therefore essential. Moreover, the production of well calcified secondary dentine, so useful in protecting the pulp cavity from the effects of attrition or of caries, also demands an adequate supply of vitamin D. Already it has been shown that the supply of vitamin D to children arrests the rate of progress of caries. It is therefore likely that the major findings in connection with dental decay, observed in experimental animals, are true in man.

Vitamin E or X (Antisterility vitamin)

Evans found that rats could be reared on a synthetic diet plus the usual vitamins and might grow normally and appear perfectly normal but yet be unable to reproduce. When such food was given to females, ovulation and impregnation occurred but the implanted foetus died. With males, the germ cells are injured to partial or complete sterility. The degeneration of the testis brought about by a continued lack of it is irrecoverable but in the case of the female, recovery from this shortage seems to be possible even in the most advanced stages.

Occurrence and properties. Vitamin E is a fat-soluble vitamin occurring in most natural foodstuffs like cereals, green leaves, etc., and in particularly high concentration in lettuce, bemax and wheat germ. It is a constituent of the unsaponifiable matter of wheat germ oil, is not destroyed by acetylation, is heat stable, and in strong contrast to vitamin A is not easily oxidised. It is stored in the animal body so that a temporary shortage would not have much effect.

Evans' latest work shows that this vitamin is also growth-promoting to a certain extent. It is also believed to have a lactation-promoting element as well but this has not received much support.

The efficacy of vitamin E extract has thus far been found useful only in rats. No definite proof yet exists that it will play the same part in human mechanism. There appears to be no likelihood that a shortage of vitamin E is of importance in human nutrition. None the less, claims have been made that it is of value in the treatment of sterility.

WATER-SOLUBLE VITAMINS

Plants of all kinds and certain animal products like milk, eggs, liver, etc., contain water-soluble substances which promote nutrition. Diets that are deficient in these lead to arrest of growth, loss of appetite and of weight, anæmia, nervous and circulatory disturbances, skin lesions and progressive inanition which terminates in death by starvation. The phenomena are promptly corrected when food or extracts containing the B vitamins are added to the diet. These events are in reality complex resultants of the deficiency of soluble substances which generally occur together in nature and which were, therefore, originally considered as one entity and designated as 'vitamin B.' It is just about 5 years since various workers on vitamin B began to obtain definite information on the dual nature of vitamin B. Hassan and Drummond (1927) in an attempt to discover what it was that counteracted the ill effects of high protein diets, discovered that not only yeast itself could do this, a fact which had been demonstrated by various workers already, but also that yeast autoclaved in an alkaline medium could do it. This treatment was known to inactivate the factor generally known as vitamin B, that is the factor that can cure polyneuritis in pigeons. Seidell, and later Chick and Roscoe (1927) added further evidence on the dual nature of vitamin B and it is now generally accepted that what used to be called vitamin B, really consists of at least 2 factors. (Hence termed 'vitamin B' complex). These have been named B₁, the antineuritic and B₂, the anti-pellagra vitamin. Both B₁ and B₂ are necessary for growth and both these factors occur in association in nature.

Further evidence is gradually growing that in addition to the two water-soluble vitamins already described there is another vitamin or perhaps rather a group of vitamins (provisionally termed B₃, B₄, B₅), which promote growth without being antineuritic or pellagra-preventing. Lately, it has been very definitely proved that a very large excess of both B₁ and B₂ will not bring about normal growth. It is unnecessary

to postulate, at the present stage of our knowledge, the existence of other factors.

The Antineuritic Vitamin B₁ (F)

Deficiency of this vitamin causes arrest of growth in young animals, and produces polyneuritis in adults. Birds are particularly susceptible to the lack of this vitamin and pigeons develop polyneuritis within 20 days when fed on a vitamin B-free diet. Rats on a hulled rice diet die from inanition with relatively little anaemia and no polyneuritis. Deficiency of B₁ factor causes atrophy of the mucous membrane and muscular coats of the bowel. There is also evidence of atrophy of the lymphoid tissue including Peyer's patches in the intestine of the rats. It will thus be seen that different animals require different periods to develop the disease and the manifestations are slightly different though the pathological basis remains the same in all animals.

The phenomena disappear promptly and completely if foods or extracts containing the antineuritic vitamin are administered early. If they are delayed until the degenerative changes of inanition, particularly the neuritis, are too far advanced, the progress is merely delayed and the decline proceeds to death.

Nature and properties of vitamin B₁. This is water soluble and dialysable. It is insoluble in ether or absolute alcohol but dissolves in ordinary alcohol, especially if this is acidulated. It is readily adsorbed on Fuller's earth and charcoal and may possess a tertiary amine group.

This vitamin is highly resistant towards acids, remaining unaltered on boiling for twenty-four hours with 20 per cent. mineral acids. Alkalies do not destroy it at room temperature. It tolerates heating to 100°C. for several hours in neutral and acid solutions. It is, however, quickly destroyed when heated to 120°C. This property is made use of in separating the antineuritic from the antipellagra factor. Autoclaving yeast at 120°C. destroys the B₁ factor while B₂ factor practically remains unaltered.

Highly active concentrates have been obtained of B₁ vitamin by special adsorbents and differential solvents. Peter's extract from yeast protects pigeons in dosage of 0.004 mg. per day. A crystalline substance from rice, isolated by two Dutch scientists, Jansen and Donath, protects pigeons with 0.03 mg. dosage per day. A chemical

formula has also been ascribed to this crystalline substance. Recently, much more active extracts have been obtained by other workers.

Levene (1928) has shown that pure B_1 vitamin can be obtained by deaminising yeast. Deamination kills vitamin B_2 , whereas B_1 remains unaffected. This observation has, however, been contradicted by other workers.

Vitamin B_1 Deficiency Disease

Beri-beri. There is a good deal of difference of opinion as to the true etiology of human beri-beri. Many workers have adduced cogent arguments to show that human beri-beri differs strikingly from the avitaminosis which is produced experimentally in birds (polyneuritis gallinarum); in beri-beri there is oedema, cardiac excitation and hypertrophy, whereas in avian avitaminosis, there is drying up of the tissues and cardiac atrophy. Another important point of difference is that in many outbreaks of human beri-beri there has been no evidence whatever of a previous shortage of vitamin B in the diets of the patients. Other arguments against acceptance of the vitamin deficiency view are that the manifestations of the disease are those of a toxic neuritis rather than of a food deficiency and the outbreaks are sometimes of an explosive nature, such as could hardly occur if we were dealing with a food deficiency. The seasonal distribution also suggests the formation of a poison in the rice during hot and damp weather. The theory, therefore, that human beri-beri is essentially caused by a food intoxication rather than a food deficiency is gradually gaining ground. Whatever be the essential cause of the common form of beri-beri, it is probable that deficiency of vitamin B_1 in the diet is a predisposing factor.

Vitamin B_1 may be supplied through many articles of diet. Rice hulls or their water or alcoholic extract ('tiki tiki'), the hulls and the embryo of other grains and yeast are all rich stores of this vitamin and when administered early in the course of the disease produce very satisfactory results and may arrest the progress of the disease in many instances. As beri-beri is essentially a disease of the rice-eating countries and as rice is considered also to be a source of infection, complete stoppage of rice in the diet is recommended to be a safe course.

Vitamin B deficiency. McCarrison showed that partial deficiency of vitamin B caused marked wasting in the gastrointestinal tract; Plimmer confirmed this and showed that partial deficiency of vitamin B continued over several months in birds did not cause polyneuritis, but affected the intestine profoundly. The chief effects were atony of the gut, with consequent constipation and stasis, distension of the bowel and auto-intoxication.

Plimmer found that although a very small quantity of vitamin B was sufficient to prevent polyneuritis in birds, yet a considerable supply was needed to maintain them in full health. He also found that the amount of vitamin needed was proportional to the amount of food supplied, and that a quantity of vitamin which was sufficient to maintain a bird in health on a spare diet, became insufficient if the diet was increased by the addition of vitamin-free food. Excess of carbohydrate, in particular, increased the need for vitamin B. In the tropics, particularly in India, where carbohydrate foods are consumed in excess, the need for vitamin B is much more pronounced than in colder climates. The wide prevalence of gastro-intestinal disorders in India may have some relation with vitamin B deficiency. Diet in the tropics should, therefore, be regulated in such a way that vitamin B is supplied in excess of the normal demands. Unless this is done, the body metabolism may fail whenever an extra strain is thrown on the system, *e.g.*, during the time of pregnancy and lactation in women and at the time of active growth in young men.

Anti-pellagra Vitamin, B, or G or (PP)

If young rats are kept on certain limited diets such as oats, a train of symptoms appear within 3 to 4 weeks, which are quite characteristic. The growth is markedly interfered with, inflammation and ulceration of the buccal mucous membrane sometimes going on to sloughing, dermatitis and nervous lesion are also noticed. Chittenden and Underhill (1917), and Chick and Hume (1920) obtained the same train of symptoms in dogs and monkeys respectively. The lesions resemble those of human pellagra, a disease characterised by a dermatitis of

exposed surfaces, first described by Casal in Spain. Goldberger and Little (1926) found that the experimental pellagra-like disease produced in animals could be cured by the administration of yeast which was previously heated to 120°C. at 15 pounds pressure to destroy its antineuritic properties. The factor responsible for this was named the pellagra-preventing (PP) vitamin. The experimental work has been confirmed and extended by Chick, Hume and other workers.

Pellagra occurs chiefly in maize-eating countries, particularly in Italy, Spain, Roumania and the corn-fields of the Southern States of North America. Rare isolated cases occur in England, India and other countries but most of these have been shown to be associated with the eating of maize in the form of cornflour.

A great variety of theories have been advanced to account for this disease but the position is much the same as in connection with beri-beri. Goldberger and others believe the disease is due to the deficiency of vitamin B_2 (PP or G) but there is another school who do not agree to this view. There are reasons for believing that the composition of the protein of the diet may be a factor of equal importance to the vitamin B_2 content. Probably the vitamin deficiency factor is not the sole causative agent. There is a definite association of the disease with a special food grain so that a positive toxic factor would be more likely to occur than an absence of some nutritive property. However, it is certain that this vitamin is an essential dietary unit for growth and normal health and that it is an important factor in the treatment of pellagra.

Properties. This vitamin has not been isolated. It is soluble in alcohol, in water and is thermostable to a much greater extent than its colleague. Levene (1928) has found that silica gel has the power of absorbing both B_1 and B_2 , but it absorbs B_2 preferentially. This observation can be utilised in obtaining an yeast extract which is much more active in its B_2 content. Ordinary dried yeast contains both B_1 and B_2 in the proportion of 1 : 7.5 and the material obtained from the silica gel contains them in the proportion of 1 : 30.

Anti-scorbutic Vitamin C

Occurrence. This vitamin occurs in all growing vegetable tissues. Green vegetables, fresh fruits (lemons, oranges, tomatoes, etc.), potatoes, onions, etc., contain large quantities of this vitamin and smaller quantities are contained in fresh meat and milk. This vitamin has been definitely proved to be a protective against scurvy.

Properties. Vitamin C is very unstable and is destroyed on cooking or drying. It is, however, fairly stable in the rind of citrus fruits and in tomato juice. Ordinary cooking destroys most of the vitamin C in vegetables and the duration of the heating is more important than the temperature to which they are raised. Cabbage loses about 80 per cent. of its vitamin C content by heating to 100°C. for twenty minutes or by heating to 60°C. for an hour. The vitamin of the citrus fruit and tomato is stable even on cooking. This is perhaps due to the protective action of the acid.

A curious fact, and one which has, on more than one occasion, been put to practical use, is that the vitamin C is completely absent from dried grain but is formed during germination. A supply of vitamin C can therefore be obtained by allowing grain or peas to germinate. The body cannot store vitamin C and depends for its supply upon fresh vegetables.

The chemical nature of vitamin C is not known. Recently, Szent-gyorgyi (1933) has isolated a substance named ascorbic acid (originally named hexuronic acid) which is claimed to be identical with vitamin C. This vitamin is water soluble and dialysable. Zilva (1927) has prepared concentrated anti-scorbutic vitamin from lemon juice, and with this preparation, very good results can be obtained in clinical scurvy.

Vitamin C may shortly be shown to consist of two factors, one anti-scorbutic and the other growth-promoting. These have however not yet been definitely established.

Effects due to lack of vitamin C. The chief symptoms of scurvy are sore and bleeding gums, diarrhoea, cedema and hæmorrhages which may occur in any part of the body. Weakness is also a prominent feature. The disease was very common

in sailors in the days of long-sailing voyages and Polar expedition. Scurvy in adults is rarely encountered at the present time. Severe outbreaks were observed in Murmansk in 1919, and in the famine areas of Russia in 1922, but in Western Europe and America, it is almost unknown. The children are more commonly affected due to improper feeding and hence infantile scurvy is commoner. Barlow's disease occasionally seen to-day in infants is probably due to lack of vitamin C. This is also fast disappearing owing to the general recognition of the value of fruit juice in supplementing the possible deficiency of a milk diet. Most of the dietaries of the tropics are quite well supplied with anti-scorbutic substances and, therefore; scurvy is very seldom found in India. The susceptibility to scurvy varies widely for different kinds of animals. Guinea pigs develop typical scurvy after 3 weeks without green food. Human beings take a much longer time to develop the disease (120 days on an average). Rats, mice, cattle and fowl appear quite unsusceptible, apparently they are able to manufacture the vitamin in their liver.

Toxamins. Mellanby (1930) has proved the existence in the germ of cereals of substances which antagonise the fat soluble vitamins. The germs of oats contain more of these than does wheat germ, whilst ergot is particularly rich in toxamins. Ergot and germ of cereals can also produce sub-acute combined degeneration in the spinal cord, an effect that is prevented by an adequate supply of vitamin A.

The nature of toxamin is at present unknown.

Conclusion. A short account of vitamins from the standpoint of therapeutics is given. Vitamins are becoming popular everyday and vitamin preparations are coming into the market in increasingly large numbers. It must, however, be remembered that their role of utility is very limited in the tropics. So far no very acute symptoms of deficiency of vitamins A, D, C and E have been evident in this country. Epidemic dropsy is fairly prevalent in India but this also has been shown to be not definitely due to lack of vitamin B and the administration of active B extracts has not been able to prevent or cure the disease completely. The food in the tropics may be deficient in protein and other constituents but is certainly not lack-

TABLE SHOWING THE CHIEF FEATURES OF THE VITAMINS

Vitamins	Diseases caused by deficiency	Diets rich in vitamin	Special properties of vitamin	Medicinal preparations available and remarks.
Vitamin A. Soluble in fats & oils.	Xerophthalmia, night-blindness. Susceptibility to bacterial infections. Retardation of growth.	Cod-liver oil, fresh milk butter, fresh eggs, liver, fish roe, fish liver oils, fresh vegetables like carrots, spinach, tomatoes, cabbage, yellow maize, bicus (alfalfa), green leaves, etc.	Heat stable at ordinary cooking, destroyed by boiling at 100°C. for 6 hours. Constitution not settled. The plant pigment carotene is closely related to it. Active crystalline preparations have been obtained.	'Avolesum' (B.D.H.) 'Haldiol' (B.C.P.W.)
Vitamin B₁ or Vitamin F of Americans. Soluble in water.	Restricted growth, malnutrition, beriberi, digestive disorder, e.g., loss of appetite.	Brewer's yeast, legumes, cereal grains (unmilled), eggs, liver, fresh vegetables, milk, malt extract, etc.	Little affected by cooking, drying or preserving in tins. Destroyed by heating with alkalis, but stable in neutral or acid solution. Active crystalline preparations have been obtained.	Available in yeast preparations, 'Vity's' (B.C.P.W.)
Vitamin B₂ or Vitamin G of Americans or Pellagra-preventing (P.P.). Soluble in water.	Loss of weight. Pellagra.	In nature usually associated with B ₁ ; yeast, legumes, etc.	More stable than vitamin B ₁ . Crystalline preparations have been obtained.	'Vity's' tablet (B.C.P.W.)
Vitamin C. Soluble in water.	Scurvy.	Lemon & orange juice, tomatoes, fresh vegetables, germinating leguminous seeds, fresh fruits, fresh milk, etc.,	Heat labile, very easily destroyed. Tomatoes & lemon juice sterilised by boiling retain vitamin activity.	'Ascorbic acid' is identical with vitamin C.
Vitamin D. Fat soluble.	Rickets, osteomalacia, dental decay, faulty absorption of lime and phosphates.	In nature always associated with vitamin A, cod-liver oil, irradiated ergosterol, germinating grains, fresh vegetables, butter and fresh milk, etc.	More stable than vitamin A. Unaffected by cooking. Irradiation converts ergosterol into vitamin D.	Irradiated Ergosterol in oil 'Vigantol,' 'Ostifin,' 'Rayneol,' etc. International unit adopted.
Vitamin E. Fat soluble.	Disturbances in gestation. Sterility, nonlactation.	Wheat embryo, egg yolk, fresh vegetables, liver, milk, etc.	Stable.	Obtainable in food products and in concentrated form in wheat germ oil.

ing in vitamin content. Green vegetables are available in plenty and form the daily ration of even the poorest member of the civil population. The Eastern habit of keeping their bodies exposed to the sun and the plenty of sunlight available are highly conducive to the abundant production of vitamin D from the ergosterol in the skin.

Although the vitamin content of the average dietary is generally adequate for the normal requirement of the population, there will always be a need for the use of extra supplies of vitamins either through natural sources or through vitamin preparations to meet periods of emergency such as pregnancy, lactation or for use in infancy and childhood when growth is rapid. A little excess of vitamins consumed through foods will not do any harm but may stand in very good stead when an extra demand arises. It should be realised, however, that the amount of vitamins required to preserve normal health is very small, probably only a small fraction of a milligram a day for an adult and most of the dietaries in different countries contain ample quantities for this purpose. Large quantities of vitamins supplied in form of proprietary preparations may do more harm than good.

Preparations.

Liquor ergosterolis irradiati. B. P. is a solution in oil of an antirachitic principle. It contains 3,000 units of antirachitic activity per gramme. It should be kept in a well-closed container, protected from light and stored in a cool place. The prophylactic dose for infants is 5 to 15 minims daily (1,000 to 3,000 units) and the curative dose for infants is 25 to 50 minims daily (5,000 to 10,000 units).

Radiostoleum. It is a solution of vitamin A concentrate and radiostol (irradiated ergosterol containing vitamin D) in a vegetable oil. It is standardised to contain 3,000 international units of antirachitic activity per gramme; it is doubly standardised as to its vitamin A content. It is stated to have 30 times the vitamin D and 60 times the vitamin A activity of high grade cod-liver oil. It is administered orally in doses, of half to one tablespoonful daily.

Vleosterol in oil 250 D. Irradiated ergosterol is dissolved in a vegetable oil and standardised to contain 3,333 rat units of vitamin D in each gramme, the strength being 250 times that of a potent cod-liver used. The average prophylactic dose for infants and children is 8 to 10 drops (0.1233 to 0.1666 c.cm.) in severe cases and for adults, doses in

excess of 20 drops may be given. There are various other preparations in the market (Abott's, Mead's, Parke Davis & Co.'s, Squibbles' and Winthrop's.)

Oscodal. It contains in each gramme not less than 25,000 vitamin A units (U.S.P.) and has a vitamin D content such that 0.075 mgm. per day will suffice to initiate recalcification in the leg bones of young rachitic albino rats in 10 days. For infants and children the usual dose is from 0.01 to 0.04 gm. and for adults from 0.04 to 0.06 gm. three times a day.

Haliverol. It is the oil obtained from halibut livers, to which irradiated ergosterol is added in such proportions as to make its vitamin D potency equal to 250 times that of high grade cod-liver oil. Its vitamin A potency is 60 times that of high grade cod-liver oil. The average dose is 8 to 10 drops daily for infants, for premature and rapidly growing infants 15 drops daily and for adults especially nursing expectant mother's 20 drops or more daily.

Adexolin. It is a concentrated solution of vitamin A and D. It is supplied in capsules, each containing 3 minims, the usual dose is 2 to 3 capsules twice a day.

Bemax. It is a cereal preparation made from wheat, ryes, or barley. It is stated to contain a greater proportion of vitamins B₁, B₂, and B₆ than any other product of its kind. It is also rich in E and A. The dose is one tablespoonful daily.

Metagen. It is a combination of water soluble and fat soluble vitamins in extract form and physiologically tested. It is supplied in capsules; the usual dose is 1 to 2 capsules, three times daily, before meals (P. D. & Co.).

Marmite. It is a palatable yeast extract rich in vitamin B. One to two teaspoonfuls twice a day is the usual dose which can be added in soups, etc.

Vitamin contents of different articles of food will be found in the Appendix.

CHAPTER VIII

PYREXIA

The normal body temperature. The human body is adjusted to work best at a certain temperature, which is called the normal. Any variations from it are detrimental to the proper working of the organism. Provision is therefore made in the body to regulate the temperature and keep it at the required level. In the cold-blooded or poikilothermic animals, the temperature depends on the surroundings. It rises in hot weather and falls in the cold and the life of the animal varies accordingly. In the warm-blooded or homo-thermic animals, the temperature is maintained at a constant level independently of their surroundings. Transitional forms between these two types occur such as in hibernating animals. The mean body temperature maintained by warm-blooded animals differs in different animals, *e.g.*, among the birds it usually lies between 40°C . (104°F .) to 43°C . (107.6°F .) or more. In most mammals, the mean body temperature is lower than birds' but somewhat higher than that of man.

Normal variations also occur in the body temperature in human beings. The normal temperature in man is usually taken to be 37°C . or 98.4°F . but it is well known that the temperature differs in different parts of the body and also at different times of the day. The rectal temperature is nearly 0.6°C . or 1.0°F . higher than the mouth temperature; the temperature in the axilla is 0.6°C . or 1.0°F . lower than the mouth temperature. As regards the diurnal variations, the temperature rises during the day and attains its maximum late in the afternoon (37.5°C . at 6 p.m.); it falls during the night and reaches its minimum in the early hours of the morning (36.2°C . at 4 a.m.). The difference in the maximal and minimal temperature usually amounts to somewhat over 1.0°C . or 1.7°F . The cause of these variations is not clearly understood, but is attributed by some to muscular activities during the day and rest during the night. Food has also something to do with it, as diurnal variations of temperature are not so marked during

starvation. The temperature also varies at different periods of life. The temperature in the infant is higher than in later life.

Regulation of body temperature. Apart from the small diurnal variations, the temperature of the body is maintained at a remarkably constant level by the physiological processes in the body. This is accomplished by a fine adjustment of heat production and heat loss. Any change in the environment which involves a marked increase or decrease of temperature quickly brings the heat-regulating mechanism into action. The temperature of a normal person rises when muscular work is undertaken. A brisk walk for two hours may raise the rectal temperature of a healthy person from 37.0°C . to 38.4°C . (101°F .). In certain diseases such as tuberculosis the diurnal variations as well as the rise of temperature produced by exercise is increased. The brain can only function normally within a narrow range of temperature. A fall of 3°C . below normal produces narcosis, whilst a rise of more than 4°C . above normal may produce delirium.

Heat production is governed by : (1) The motor nerve centres and motor nerves to muscles and glands. (2) The quantity and quality of the food consumed. The heat generated depends on the amount of food oxidised and the activity of glands and muscles. Thus a starving animal shows a lower temperature than one fed normally. Although muscular activity plays a very important part in the production of heat, it has been shown that even if the voluntary muscles are paralysed by administration of curare, a high temperature can still be maintained in febrile animals. The production of heat in these cases must apparently be due to the activity of glands and involuntary muscles. Metabolism and the body activity of the voluntary and involuntary muscles and of the glands are, therefore, important factors in the production of heat.

The heat produced depends upon the basal body metabolism and upon excesses above this resulting from muscular activity and the ingestion of food. The basal metabolic rate (B. M. R.) of an individual means the production of heat with the body at complete muscular repose and fasting. The rate is subject to marked physiological fluctuation. According to Benedict the

average basal metabolism of a normal adult is about 25 calories per kilo. of body weight per day. The B. M. R. is usually calculated in calories per sq. meter of body surface. If height and weight of an individual are known, his body surface can be calculated from tables. The normal B. M. R. is 40 calories per sq. meter of body surface per hour. Lighter individuals though showing a smaller total metabolism than heavier ones, usually have a greater metabolism per unit of body weight. The heat production is increased by exercise, by food and exposure to cold. A normal man of sedentary habit produces about 3,000 calories a day, while a manual labourer produces as much as 6,000 calories per day.

The heat is lost mainly through, (i) radiation and conduction from the skin, (ii) evaporation of water from the skin and respiratory tract. Heat is lost also through the excretions, in the process of warming the inhaled air and the ingested food taken at a lower temperature. In temperate climates, approximately 75 per cent. of heat is lost by conduction and radiation if a man is doing some physical work. During rest, heat loss through evaporation comes more prominently into play. If the heat loss is suddenly increased by the application of cold to the surface, there will be a reaction on the part of the body resulting in constriction of the peripheral blood vessels and shivering. The constriction of blood vessels is brought about by the vaso-motor centre in the medulla which ensures that the blood supplied to the vital organs is maintained at a proper temperature. The constriction will lessen the amount of blood circulating through the skin vessels and thus reduce the heat loss through the skin. Shivering will increase heat production and by diminishing heat loss and increased heat production the effects of sudden cooling will be counteracted. Increase in the surrounding temperature will, on the other hand, involve the reverse kind of reaction by the same heat-regulating mechanism. There will be a dilatation of the skin vessels and increased perspiration. Both these factors will prevent the body temperature from rising above the normal, by increasing the heat loss from the body. The temperature is thus kept constant by changes in the production and dissipation of heat.

The delicate adjustment of heat production and heat elimination is under the control of the central nervous system. The principal centres concerned in heat regulation lie near the basal ganglia and control both the production and the dissipation of heat. They in their turn are influenced by afferent stimuli from the skin and mucous membranes as well as by the temperature of the blood which circulates through them, and they work in close co-operation with the vasomotor respiratory and the sweat centres. Sensitiveness of the heat centre was shown by Barbour to be extremely delicate. By heating or cooling the blood going to the centre, he showed that slight changes in the temperature evoked a compensatory response.

Regulation against over-heating. If the amount of heat generated is greater than that eliminated, a rise of body temperature is the result. Production of heat is increased after food and especially after protein food, but this increase is never great and is promptly eliminated. Over-eating especially by consumption of meats may increase discomfort during hot weather by throwing an extra burden upon heat elimination, but this rarely causes any appreciable rise. Muscular activity, on the other hand, is one of the important causes of over-heating. It has been seen that during moderate exercise the total metabolism of the body may be increased 2 to 3 times and after violent exercise 5 to 8 times the normal resting metabolism. With the increase in metabolism, the temperature of the body rises and it is quite common to see an increase of 2° to 3°F. in the rectal temperature. An equilibrium is, however, maintained by increased dissipation, by radiation, conduction, evaporation from the surface of the body and by deep breathing. When this elimination is defective, a serious rise of temperature may occur and heat stroke may result. This phenomenon is very well illustrated in the case of certain animals like the dog in which perspiration is almost absent. If evaporation from the tongue is prevented in such an animal, by making him breathe through a tracheotomy cannula and the animal is made to take exercise, the temperature rises so high, following a brief period of muscular exercise, that the animal may die of heat stroke. In man, in certain diseases of the

skin, *e.g.*, ichthyosis, the power of dissipation of heat through the skin is interfered with and in these patients muscular exercise may produce an unusual rise of temperature. If the external temperature is higher than that of the body, the heat loss is not carried out by conduction but by evaporation of sweat, which is secreted to a greater extent on account of an increased flow of blood in the cutaneous vessels. In man this is the chief means of regulation of temperature if the surrounding temperature is high. The nerve centres are guided in this regulation, (1) by the temperature of the blood coming to them and (2) by reflexes from the skin. If in experimental animals the temperature of the blood going to the centres is raised, the various changes that characterise regulation against over-heating come into force. In man reflexes from the skin play a very important part. The rate of evaporation depends on the humidity of air. Movements of the air assist in evaporation from the skin and excessive heat is borne better when the air is in motion. In tropical climates, where the external temperature is high, the increased dissipation keeps the temperature down, at the same time the individual feels relaxed, restricts his exercise and food and thus helps in diminishing heat production.

Regulation against over-cooling. Man can tolerate a much greater range of low temperature, protection against heat loss being assisted by a thick layer of fat under the skin which is a bad conductor of heat. In animals, fur and other covering, and in man clothes prevent dissipation. Besides this, two other factors are important: (1) Physical regulation, *i.e.*, by constriction of cutaneous vessels so that less blood flows through the periphery. Even exposure to moderate cold reduces the cutaneous supply of blood of the arm to one-half or less of what it is at a comfortable temperature. (2) Chemical regulation, *i.e.*, by increased metabolism in the muscles as shown by shivering. This only comes into force when the physical regulation does not suffice. After division of the dorsal cord the metabolism fails to show the characteristic change when the animal is exposed to cold, because of the paralysis of muscles. Extra heat is also obtained by ingestion of food. As in the case

of over-heating, the mechanism is under the control of nerve centres which are influenced by sensory impulses from the skin. If the skin is suddenly cooled a reflex constriction of the cutaneous vessels of the body occurs immediately. A cold bath often causes a rise of temperature by increased muscular activity by shivering and constriction of skin vessels.

PYREXIA AND ITS TREATMENT

Conception of fever. Fever is derived from Latin word *febris* meaning to boil. It is a complex phenomenon, the main feature of which is a rise of the body temperature associated with disturbance of metabolism, special senses, pulse, respiration, etc. The rise in temperature in fever is due to a defect in the heat regulating mechanism, which is not clearly understood. Physiological fever, we have already seen, is produced by immersion in a warm bath at 40°C. and is not accompanied by any of the other phenomena of fever above described. Entrance of living or dead bacteria or their products in the blood or protozoal organisms produces fever. No constant relation exists between the severity of infection and the height of fever. The cause of marked fluctuations in temperature during infections is not understood. In some it is merely an exaggeration of normal diurnal variations. Other conditions giving rise to fever are injection of foreign proteins, destruction of cells in the body in the absence of bacteria (*e.g., extravasated blood*) and a number of chemical poisons. The injection of certain salts, sugar, sulphur, atropine, caffeine, cocaine, strychnine, picrotoxin, tetrahydro-beta-naphthyl-amine, epinephrin, and many other substances will increase the temperature when given in large doses. Puncture of the brain in the region of the corpus striatum produces fever which is associated with constriction of the peripheral blood vessels and an increased production of heat within the body, mainly from combustion of carbohydrates derived from hepatic glycogen. In a general way the rise resembles that which occurs during infective processes; essential and undoubted differences have not been established between the two. The probable explanation is that the rise of temperature in infectious disease is due to stimulation of the heat regulation centres by some products of infection. Clinically, rise of temperature occurs after cerebral hæmorrhage, especially into the ventricles, due to mechanical or chemical irritation of the basal portions of the brain. Injection of water also produces a rise of temperature, the cause of the so-called water-fever probably being the presence of minute traces of organic matter in the water used for injection. Excessive loss of water may lead to elevation of body temperature. According to Barbour the causation of fever is as follows:—Due to the infection, some metabolic changes occur in the tissues which increase their affinity,

especially that of muscles, to water. The blood volume, therefore, becomes decreased and there is a redistribution of circulation chiefly at the cost of the peripheral circulation. The skin becomes cold and the heat regulating mechanism interprets it as it interprets ordinary cold and raises the body temperature. The important change that occurs in fever is, therefore, change in blood volume. This may follow loss through diuresis, or excessive sweating or restriction of fluid intake.

Fever may be continuous, remittent and intermittent. The temperature may fall by lysis or crisis. The febrile temperature is primarily due not to an increase in the heat production or to an absolute inefficiency in heat dissipation but to a lack of adjustment between the two. The heat regulation in fever behaves as if the regulatory centres were set to maintain the body temperature at a new level, which is maintained in the same way as normal temperature. Some of the recent writers, however, speak of an increased excitability of the heat centres which causes them to regulate the body temperature at a new and higher level. In fever the heat regulation is less perfectly adjusted than in health as it is much more difficult to reduce the temperature of a healthy man than a fevered individual either with cold baths or with antipyretic drugs. The extra heat produced within the body is also less perfectly eliminated.

Metabolism is accelerated in fever as warmed tissues metabolise more material than cooled tissues, but in addition to this there is probably a toxic element that causes tissue destruction, and the rapidity of protein consumption varies in different infections. This increased metabolism rarely exceeds 40 or 50 per cent. over normal. No strict parallelism exists between the rate of protein decomposition and elevation of the temperature. The amount of protein lost to the body may be considerable, being as much as 200 to 500 gm. of muscle-tissue per day. In surra more than one-fifth of the proteins of the body are lost in the course of the disease. Immediately following the cessation of fever there is a marked increase in the nitrogen excretion. The nitrogenous equilibrium can be maintained in fevers and the patient's strength conserved by giving adequate diet, but unfortunately in many fevers the toxins produce loss of appetite which prevents intake of food and a decrease in absorption may occur. The partial starvation thus produced increases protein metabolism; besides high temperature produces further rapid wasting of tissues. To supply this need administration of glucose and other similar foods is necessary. It has been demonstrated that by giving selected carbohydrate food not only is nitrogenous equilibrium maintained, but the abnormal excretion of creatinin, which is probably derived from the breakdown of muscle-tissue, is reduced. This does not bear out the toxic or essential protein destruction in fever.

Acidosis also occurs in fever but its occurrence is probably not as common as is supposed. Ketonuria which often occurs in febrile conditions is an indication of disturbance in fat metabolism, but is not considered as evidence of acidosis. It is not possible to make any generalisation regarding the occurrence of acidosis or alkalosis in fevers.

It is well known that excretion of chlorides in fever is decreased. This is certainly true of pneumonia and other infectious diseases. The retention of salt is associated with simultaneous retention of water, especially in long continued fever such as typhoid; the tissues, therefore, become relatively rich in fluids and poor in solids. A normal individual will excrete up to three litres of water which may be introduced into his body; the fever patients do not do this and retain a considerable amount. The extra water is, however, stored mainly in the tissues and less in the blood and the same is the case with the chlorides. The state of affairs is, therefore, different from what occurs in nephritis where the concentration of the salt is high in the blood. It has been shown that antipyretic drugs bring about a dilution of the blood, which favours dissipation of heat by radiation.

Effects of fever. Heat above normal body temperature, especially if continued for a long time, causes degenerative changes in the tissues. The cells undergo cloudy swelling. The proteins of the muscles coagulate at 104°F . (40°C .) and in nearly all tissues globulin coagulates at 45°C .; mammalian muscle passes into rigor between 45° to 50°C . Coagulation takes place at a lower temperature when continued for a long time. Even if coagulation is not visible a change analogous to it may cause death of the cells. It is possible that heat and toxin may act in a synergistic manner to disturb the functions of the cells.

The heat also acts directly on the heart muscle and stimulation of the nerve centres controlling the heart produces slowing or acceleration. When temperature is the only factor, a rise of temperature, *e.g.*, 97.8° to 104°F . (37° to 40°C .) will cause an increase of pulse rate. In addition to this, toxins play a part, *e.g.*, in typhoid fever the pulse is relatively slow, being about 70 to 80 beats per minute with a temperature of 103° to 104°F . In scarlet fever the pulse is surprisingly rapid.

As regards the central nervous system, the toxins and other pyretics are said to produce a stimulation of the regulatory mechanism. A number of drugs, *e.g.*, cocaine, atropine,

caffeine, epinephrine, which are known to stimulate the central nervous system, cause a rise of temperature, while those which depress the nervous system, *e.g.*, alcohol, chloral, morphine, cause a fall of temperature. The mechanism of production of fever seems to be a stimulation of the sympathetic system to which the heat regulating mechanism probably belongs. The other convulsant poisons such as santonin, picrotoxin and phenol, which stimulate the para-sympathetic system, and cause myosis, slow pulse and psychic depression, do not increase the temperature.

The significance of fever. The practical question involved in the treatment of infectious diseases is to what extent should one attempt to reduce the temperature. It was thought that the febrile rise of temperature was on the whole a favourable manifestation and helped the organism in overcoming infection. Clinical experience shows that when bacterial infections are unaccompanied by fever they run a very unfavourable course. Leprosy, tuberculosis and parasitic diseases not marked by febrile reactions are usually difficult to cure and do not confer immunity. Treatment of neurosyphilis by artificial infection with malaria probably chiefly acts by increase of temperature. Collapse may occur in certain conditions if the stimulus of high temperature is removed. It has been shown that with most bacteria the optimum temperature for development is confined within very narrow limits, which are exceeded by the temperature of fever. The tendency of fever may, therefore, be useful, but unfortunately the cells of the organism are not adjusted to work under high temperature and it may be more detrimental to them than to the bacteria. It has been advocated by some that fever is the essential manifestation of infection, that it is dangerous in itself, and should be vigorously combated. The question still remains unsettled, as patients with a high temperature are more sick than those with a low temperature, but this is not due to the temperature but because such patients are suffering from more severe infections. Besides this, in the most unfavourable of all infections the temperature may be low. From a comparison of clinical cases it is, therefore, not possible

to judge the favourable and unfavourable effects of temperature. The antipyretic measures also do not give any clear answer, because not only do they reduce the temperature, but they have various effects on other parts of the body, especially the brain and the circulation.

Many experimental studies have been carried out in this connection. Rabbits have been kept with a body temperature of 41°C . (105.8°F .) and over for weeks at a time without any serious damage. The degeneration of internal organs observed in infectious fever is not due to prolonged overheating of the body. Serious effects are only produced when the temperature is raised to a height not usually encountered in fevers. The damage appears to be done more by the infection. The question is, does the rise of temperature exert a favourable or an unfavourable effect upon the course of infection? The high temperature may have a direct effect on the infective organism or it may help the host in developing protective mechanisms. The temperatures encountered in certain fevers are sufficiently high to inhibit the growth of certain bacteria. Pneumococcus and gonococcus do not grow well at a temperature of 104°F . (40°C .) or over. The course of infections in animals artificially infected with pneumococci and diphtheria is said to be favourably affected by artificially raising their body temperature. It has also been shown that with moderate overheating 103.2° to 104°F . (39.5° to 40°C .), the formation of agglutinins, bacteriolysins and anti-toxins is increased. From the results of these experiments it is concluded that moderately high temperature, even though maintained for a long time, is not in itself a dangerous manifestation. In artificial infections in animals an increased temperature has a favourable effect on the course of the infection and increases the speed with which the protective anti-bodies are formed. In the treatment of fevers, therefore, one should not try to bring down a high temperature too vigorously unless it is above 105.8°F (41°C .). In such cases the reduction of temperature is comparative; but in ordinary febrile temperatures there is no need for active interference. The value of antipyretic measures in such cases is to be judged, not solely from their

effect in reducing the temperature, but also from their effect on the general condition of the patients and especially on their nervous system and circulation.

Antipyretic measures. The temperature of the body can be lowered by factors which decrease the production of heat or increase its loss. As the temperature tends to fall below normal, compensatory reactions are at once set up to keep the temperature normal. It is not found possible to depress the temperature without effecting profound changes. On the other hand, it is relatively easy to lower an abnormally high temperature because it coincides with the natural tendency to return to the normal or physiological state. Antipyretics, therefore, have no effect on normal temperature but readily act when pyrexia is present. Antipyretic measures can be divided in three main groups:—

(1) Those that abstract heat, *e.g.*, application of cold in form of baths, sponging, packs. This subject has been discussed in the chapter on physiotherapy.

(2) Those that increase the dissipation of heat by dilating the cutaneous vessels and by restoring the water content of the blood. Their action is mainly central. These are antipyretics of the coal tar group, *e.g.*, acetanilide, phenazone (antipyrin), phenacetin.

(3) The cinchona alkaloids, especially quinine, probably diminish heat production. Salicylates, aconite and veratrum probably diminish heat production by slowing the circulation.

THE ANTIPYRETIC DRUGS

High temperature in the old days was chiefly combated by baths and giving such vegetable alkaloids as aconite and quinine. Bass (1875) discovered that salicylic acid and related bodies produce a fall of temperature in fever. Most of the modern antipyretics were discovered in an attempt to synthesise quinine. A large number of bodies were introduced, but those of importance are acetanilide, phenazone, phenacetin and amidopyrin or pyramidon. These are all benzol derivatives and prepared from aniline. Phenol, guaiacol, salicylates and many other compounds also lower febrile temperature, but they are

much inferior. All these drugs have the same action. The antipyretic drugs are divided into three groups:—

(1) The essentially antipyretic drugs are, (a) acetanilide and acetophenetidin or phenacetin and (b) antipyrin and amidopyrin also known as pyramidon; they are also analgesic. Like alkaloids these are precipitated by tannic acid, alkalies and other alkaloidal precipitants.

(2) The anti-rheumatic group consists of salicylic acid and its derivatives such as acetylsalicylic acid (aspirin), etc. Cinchophen or atophan also comes under this group.

(3) The antimalarial antipyretics, *i.e.*, the cinchona alkaloids.

Acetanilide. It is a colourless crystalline substance. The dose is 2 to 4 gr. (0.12 to 0.25 gm.). It has a slight biting taste and is soluble in 1 in 190 of water. It is rapidly absorbed from the gastro-intestinal tract and more rapidly if given subcutaneously. The antipyretic action is thought to be due to para-amino-phenol, and varies directly with the rapidity with which this substance is formed in the body. Temperature reduction may be so rapid as to produce collapse. For this reason its use has been to a great extent discarded.

Acetophenetidin or phenacetin. Phenacetin is a white crystalline powder. The dose is 5 to 10 grains (0.3 to 0.6 gm.). It is much less toxic than acetanilide. It produces a feeling of drowsiness and, therefore, acts as a mild hypnotic; it has a much more powerful action on neuralgic pains than any of the other antipyretics. It is an ideal antipyretic in that it produces a gradual but persistent fall of temperature and does not produce collapse. It does not produce cyanosis and has less tendency to cause skin eruptions and profuse sweating.

Antipyrin or phenazone. It is derived from phenyl hydrazone; the dose is 5 to 7 grains or more (0.3 to 0.5 gm.) and its action is very similar to acetanilide.

Amidopyrin or pyramidon is a derivative of antipyrine. It is given in doses of 5 grains (0.3 gm.).

These drugs have no effect on the normal temperature. Antipyrine is more analgesic in neuralgic pains and neuritis originating from the spinal cord than acetanilide, and is, therefore, largely used in the shooting pains of tabes which it may not always relieve. Phenacetin is used more for headaches. Phenazone is slightly less toxic than acetanilide and little more than phenacetin. A large number of combinations of antipyrine have been put on the market, *e.g.*, salipyrin is a combination with salicylic acid. Antipyrine affects the circulation and the kidneys slightly and can be prescribed in heart disease and nephritis. It is not very irritating to the stomach. It has been used in tuberculosis, typhoid

fever, erysipelas and pneumonia but it should be given with great caution.

Cryogenin occurs in crystalline masses and is slightly soluble in water. It has been used as an antipyretic to control high temperature, and this is found valuable in the treatment of phthisis and lingering pyrexia that sometimes follows the acute stages of an infection. The dose is 3 to 24 grains, but it should not generally exceed 10 to 15 grains daily.

Salicylates. These compounds lower the febrile temperature promptly. The mode of reduction is very much like that of the members of the coal tar group, *i.e.*, increased loss of heat by dilatation of cutaneous vessels and increased perspiration. In healthy individuals this is compensated for by increased heat production so that the normal temperature remains unaffected. Salicylates may easily take the place of other antipyretics and are probably safer; but may produce unpleasant side effects. Small doses of acetylsalicylic acid or aspirin (5 to 10 grains) are commonly used in mild fevers and not only reduce temperature but also unpleasant symptoms such as headache. **Novaspirin** (methylene-citralsalicylic) has no advantage.

Cinchophen and neocinchophen. Cinchophen or atophan is phenylcinchoninic acid. It has a biting bitterish taste and is irritating to the stomach. It has a pronounced action on the liver cells and increases the quantity of bile. Its absorption from the intestine is irregular and uncertain, and some can be recovered from the urine. Cinchophen is an antipyretic, but its chief action is an analgesic in rheumatism and as a mobilizer of uric acid. The dose is 5 to 15 grains (0.3 to 1.0 gm.).

Neo-cinchophen is an ethyl ester. It is also called novatophan and tolysin. It is tasteless and does not irritate the stomach. It has also a cholagogue action and has less destructive effect on the liver cells than cinchophen. The dose is 8 to 15 grains.

Both these compounds are chiefly used in rheumatism and gout.

Quinine. The antipyretic action of quinine has been dealt with in another section. In malaria, quinine reduces the temperature because of its effect on the malarial parasites, but in addition it has a general antipyretic effect in fevers other than malaria. Large doses of quinine are said to depress the metabolism by 10 per cent.; the heat loss appears to be but little altered. Quinine has also a sedative action on the centres though it is not so marked as with other antipyretics. Quinine, however, conserves energy probably by decreasing metabolism instead of increasing the heat loss. In such diseases as influenza when the depressant action of the aniline drug is undesirable, quinine is very useful. The antipyretic dose is 5 to 15 grains.

Antipyretic action of analgesic antipyretics. In normal persons even large doses of these drugs produce no effect. In fever a fall is produced beginning within 2 hours and lasting for 2 to 4 hours.

The fall is accompanied by profuse perspiration due to dilatation of cutaneous vessels and increased heat loss owing to direct action of the drug on the heat regulating centres. Barbour studied the effect of direct application of these drugs to the region of the heat centres and found that both the antipyretics and narcotics produced a fall. Central nerve stimulants such as caffeine produced a rise. The mechanism of rise of temperature is a stimulation of these centres and the antipyretics, therefore, act by depressing them.

Untoward and toxic effects. Some individuals show an idiosyncrasy to these drugs, cyanosis and collapse being produced with ordinary therapeutic doses. Papular and erythematous skin rashes may follow phenazone and acetanilide, antipyrin produces a scarlatiniform rash with cedema of the face and fever. It may also produce urticaria, or a vesicular, bullous or eczematous eruption. A large number of headache powders contain acetanilide and deaths have occurred from their use, the chief symptoms being cyanosis, nausea, persistent vomiting, weak and irregular pulse, dyspnoea, cold sweat, coma and collapse. Deaths have occurred with 5 grains (0.3 gm.) but recovery is reported after 120 grains (7.5 gm.). Severe symptoms often follow from 0.2 to 1.0 gm. doses. Antipyrin may cause burning and swelling of the whole alimentary tract, with nausea, vomiting, diarrhoea, skin rashes, mental dullness, tremors, cerebral convulsions, coma and death from failure of respiration. In the case of amidopyrin, excitement, increased reflexes, and a measles-like eruption have been noticed.

Acetanilide and phenacetin produce acute and chronic poisoning; in one form collapse and cardiac failure being prominent features and in the other cyanosis accompanied by anaemia, emaciation and weakness. There is dyspnoea and the heart is rapid and weak. The cyanosis is said to be due to the formation of methaemoglobin, but it is probably produced by para-amidophenol or some other aniline derivative which has been found in the blood and urine; sulphhaemoglobinemia is said to be present. Methaemoglobin has, however, been seen spectroscopically. Cyanosis may persist for weeks after the drugs are stopped. Caffeine is often combined with these drugs to prevent depression, but it is said to increase the toxicity of acetanilide. Sodium bicarbonate is believed to lower their toxicity.

Treatment consists in washing out the stomach with alkaline solution, maintenance of body temperature and combating the collapse with atropine, caffeine, strychnine, digitalis, etc. Chronic poisoning is met with, the symptoms being cyanosis, anaemia, disturbance of digestion, headache, dyspnoea on exertion, weak pulse, extreme muscular weakness.

Habit formation. Habit with these drugs is formed by nervous patients suffering from headache, neuralgia, etc. The habits show mental depression, digestive disturbances, anaemia and general weak-

ness. The habit is not vicious like the morphine habit but it may be difficult to break.

Therapeutic Application of Antipyretic Measures

Treatment of fever. From the foregoing discussion it is obvious that pyrexia alone does not constitute the sole indication for treatment. The toxic state of the patient is a more important factor. When it is desired to reduce temperature it is advisable to control it by use of cold sponging or bathing. Antipyretic drugs should be resorted to as little as possible. The objection to these is that they depress the patient and decrease his power of resisting disease.

In all fevers, especially when they are prolonged, water should be freely given whether the patient asks for it or not. Not less than two quarts should be given to an adult daily. It is not only essential to flush the kidneys and remove toxins circulating in the blood, but it is essential for the proper functioning of the body. The turnover of the fluid during digestion has been estimated at five quarts per day, of which no less than one quart is bile, the fluid being excreted and reabsorbed. Considerable quantities of water are lost in the urine and respiration and a certain amount in normal stools. In heat elimination an important factor is the distribution of water in the body. By dehydrating a dog a high temperature may be produced. The fever is caused by blood concentration and checked by blood dilution. In fever produced by intravenous injection of coli vaccine and in other fevers, the temperature is reduced by measures which produce dilution of the blood. In influenza, typhoid, pneumonia, salt fever, inanition fever and other fevers, the blood has been found to be concentrated, the reason being a special affinity of the tissue colloids for water. When the volume of the blood is diminished, the viscosity is increased and the surface flow of the blood decreases. The result is diminished sweating and consequent diminished heat elimination and fever. The dilution of the blood by increased ingestion of fluids remedies these defects, increases heat elimination and lowers temperature. According to Barbour, fever therapy consists in supplying water to the tissues and the

intravenous administration of water in high fever may save life. He considers that antipyretic drugs, such as acetanilide, acetophenetidin, antipyrin, sodium salicylate, aspirin and cinchophen act in fever by lessening the blood concentration and thus increasing heat elimination. After a dose of aspirin, the heat production is decreased by 4 per cent., but heat elimination is increased by 38 per cent. In non-febrile patients, in whom there is no dehydration, there is no fall of temperature in equivalent doses. Fever patients are found to be still sensitive to these drugs during temporary cessation of the fever and during convalescence.

Analgesics in the treatment of fever. The chief use of antipyretic measures is reduction of temperature in febrile conditions, but antipyretic drugs have also a sedative action on the nervous system. When the temperature is high enough to produce nervousness, headache and discomfort, antipyretics by reducing the temperature, quieting the nervous system and relieving pain, promote well-being and aid in recovery. Rapid reduction of temperature is, of course, essential in case of sunstroke, for if this is not done the temperature rises steadily till the patient dies. Such cases can only be treated by cold sponging or cold baths. There is general agreement that antipyretic drugs are of little value in the treatment of severe fever, when the temperature is retained at a high level for many weeks. Such cases are benefited by cold sponging or cold baths. Even if the bath may not produce a prolonged lowering of the temperature, the short fall gives the organs of the body rest and the results are very satisfactory. The chief use of antipyretic drugs is in mild cases of fever and in these they generally make the patients more comfortable and often assist in producing sleep, though they may not influence the course of the disease. They neither strike at the cause of the fever nor at any symptoms other than those resulting from hyperpyrexia. They make the type of disease neither less severe nor shorter. For instance, in malaria, antipyretics may prevent the development of the paroxysm but they do not attack the cause of the disease. They are merely a symptomatic and not a specific mode of treatment and symptomatic treatment should

always be carried out with care, as more harm than good may be done. When it is not possible to attack the cause of the disease it is advisable to remove the objectionable symptoms. This they do by their sedative action on the pathologically stimulated centres and on the sensory part of the cerebral cortex. Schimidberg gave them the name of "fever narcotics" and this is a very suitable name, as now-a-days they are seldom employed to combat hyperpyrexia, but rather in hope that the patient will be benefited by their sedative action on the symptoms of fever due to hyper-excitability of the brain centres. They decrease pain in the limbs, headache, delirium, and restlessness, clear confusion of mind, and induce sleep. The effects of these drugs vary with the individuals, some people can take large quantities without effect, while others are affected by small quantities. According to Barbour the analgesic effects of these drugs are produced by decreasing the concentration of the blood. Others consider that they relieve intracranial pressure.

When antipyretic drugs are used, it is better to give a small dose before resorting to a large dose. Special care is taken when these are given in diseases where the temperature falls by crisis as a dose before the crisis may produce dangerous collapse by exaggerating the physiological fall.

In cases of pain and discomfort without fever, such as headache, migraine, neuralgia, muscular rheumatism, pains of locomotor ataxia, dysmenorrhœa, and in various nervous conditions, in chorea, whooping cough, diabetes insipidus, antipyretic drugs especially acetyl salicylic acid (aspirin) generally give relief. Pyramidon is said to be a specific for measles. The drugs are usually given in the form of capsules or tablets for internal use and are sometimes combined with codeine, bromides, etc., if necessary. On account of their depressent action on the heart these drugs are often combined with cardiac tonics such as caffeine and digitalis.

HEAT STROKE (SUNSTROKE)

If heat loss is prevented, the body temperature rises, e.g., if a normal man is immersed in a hot bath up to the neck the body temperature rapidly rises from 37°C. to 38°C. (98.4°F. to

100.4°F.) or to 40°C. (104°F.) or even higher, according to the temperature of the bath. This is what sometimes happens in those living in hot climates and heat stroke is the result. The most common form of heat stroke is what is commonly known as 'a touch of the Sun.' The milder cases are termed heat exhaustion. It follows generally after an individual has been exposed to the Sun and glare. There are two forms: (1) Mild form. The patient suddenly becomes acutely sensitive to heat and feels weak; there may be nausea, headache, dizziness, pain in the limbs, thirst and sleeplessness. He may either collapse in the Sun or may drag himself into the shade before collapsing. The pulse is at first rapid and weak, the skin is clammy, the respirations are shallow and hurried, the pupils are dilated and the temperature is normal or subnormal. The mortality in this type is very low, but the patients often recover slowly. (2) Severe form. This is frequently fatal. The symptoms start as in the mild form but consciousness is lost early, the skin becomes dry and hot, and the temperature rises very rapidly. The pupils are dilated, the pulse becomes rapid and full, and the breathing is deep at first but later shallow and finally of the Cheyne-Stokes type; the pupils become contracted and the conjunctiva injected. The urine and stools may be passed involuntarily, there may be muscular twitchings and rocking of the head. Epileptiform convulsions may occur and death follow.

The temperature usually is between 99.1° to 104.7°F. (37.3° to 40.4°C.). In severe forms the body temperature rises rapidly from 104° to 111.2°F. (40° to 44°C.), rarely to 114.8°F. (46°C.). If the temperature does not rise beyond 111.2°F. (44°C.) recovery is possible under vigorous hydrotherapeutic treatment. When the temperature exceeds this limit recovery is rare, the patient as a rule becoming comatose, pale, livid and cyanotic. A dry, cool or pale skin indicates that the maximum heat dissipation is not taking place and shows that the normal mechanism of heat regulation has become deranged. Among the most common causes of sunstroke are continued high temperature with high humidity (exercise in warm weather with

unsuitable clothing). Heat prostration is not uncommon among soldiers after long marches in full uniform. It also occurs in those individuals whose regulating mechanism against excessive heat is less perfect. Alcohol is an important predisposing factor because it lessens the effectiveness of the regulating mechanism by depressing the heat regulating centres and paralyzing the cutaneous vessels. When the patient's temperature is brought down by vigorous hydrotherapeutic measures he may show continuous fever for days or even weeks after the acute hyperpyrexia has subsided. During this time the body temperature is extremely sensitive to external influences, and for years afterwards these patients may show increased sensitiveness to heat. All these factors show that heat-stroke is usually associated with and is followed by a marked disturbance in the heat regulation of the body, the centres which regulate the heat loss being deranged.

Treatment. In mild cases if the patient is put in a cool place and is given drinks of cold water, he often improves. If the pulse remains weak give a diffusible stimulant such as half a drachm each of aromatic spirits of ammonia and spirits of ether, or an injection of camphor in oil. Sometimes in these cases the temperature falls to much below normal and it is necessary to apply heat to the body, and hot drinks have to be given. The patient should be carefully watched as a sudden rise of temperature may occur.

When hyperpyrexia is present such stimulants as caffeine, or camphor in oil should be given at once. Every effort should be made to bring down the temperature as soon as possible. For this purpose the patient is put in a bath of water at 50°F. (10°C.) and he is kept there till the rectal temperature falls to 102°F. (38.8°C.). When this temperature is reached the body will probably continue to lose heat in favourable cases after removal from the bath, even sometimes to below normal. While the patient is in the bath his body should be vigorously rubbed because unless hyperemia of the skin is produced by this procedure the overheated blood will be driven to the internal organs by the contraction of the blood vessels. Rubbing the body with

ice or placing the patient in a sheet wrung out of iced water are less efficient than the bath.

An enema of 2 or 3 pints of ice cold water is often very useful. When ice is not available the heat should be abstracted from the body by evaporation of water. This is done by spraying water from a fine nozzle on to the stripped surface of the body, a current of air being maintained by hand or electric fans. Equally good results are obtained by wrapping the patient in a sheet wrung out in water and putting him under a fan. Tepid water by this method will remove as much heat as ice cold water. This method is very effective and is now extensively used in hospitals. When the rectal temperature has reached 102°F. (38.8°C.) the evaporation is stopped. Cessation of sweating is a sign of impending recurrence. Such patients should at once be covered with a moist sheet and put under a fan. Once the artificial perspiration is established recurrence is often averted.

STOKER'S CRAMPS

This is the type of heat exhaustion seen frequently in labourers working in engine rooms or in deep mines where the temperature is high. The patient gets muscular twitchings for a time and is then siezed with violent cramps principally of the abdominal muscles. The spasm may involve other muscles and may become so general as to resemble an epileptic attack. Other symptoms are nausea, dizziness and stupor, the patient being usually pale and perspiring. The pulse is rapid but strong and the temperature only slightly above normal. The condition is believed to be due to loss of chlorides to below normal by excessive ingestion and excretion of water.

Treatment. The patient should be removed to a cool place and should be given plenty to drink. Slow injection of 3 or 4 pints of slightly hypertonic saline is useful. Salt added to the drinking water (0.25 per cent. or 10 gm. per gallon) is useful in preventing attacks and is recommended as a prophylactic measure for stokers, coalminers, etc. Each person is provided with two quarts of water to which two teaspoonfuls of common salt have been added.

In addition to the various causes of hyperpyrexia already mentioned, there may be certain other types of fevers, the etiology of which is imperfectly understood. Low persistent fever or an evening rise of temperature may occur in tropical climates, in persons who are run down or have recently suffered from a prolonged attack of fever. This is probably due to the heat centres not acting effectively and can be controlled by sending the patients to a cool climate such as a hill station.

CHAPTER IX

PAIN AND INSOMNIA

Insomnia and the Use of Hypnotics

Sleep is one of the primary necessities of human life. Loss of sleep or prolonged deprivation, leads to many pathological changes in the body. Normal sleep is a protective mechanism by which the physiological wear and tear of the body are made good. It appears at definite times and if unsatisfied, will pass off; but frequent abstinence leads to permanent derangement of body function. Prolonged sleeplessness causes various pathological changes, such as histological changes in the cerebral cortex and probably the appearance of a toxin in the blood.

Sleep is a condition of unconsciousness to surroundings. There are many theories as to the etiology of sleep. Muscular relaxations, rise in the intra-cranial pressure, cerebral anæmia and similar other theories have been advanced. Cerebral anæmia will undoubtedly produce unconsciousness and sleep, but the natural sleep is not, however, attended with any material alteration in the cerebral circulation. Knowledge regarding the mechanism of sleep is still very scanty. The nervous system acts as a whole. Pathological and experimental lesions in the infundibular region produce pathological sleep. A diencephalic sleep centre has been described but the term waking centre would be more appropriate. Presence of sleep suggests an abeyance of the katabolic activity associated with the sympathetic system and an excess of the anabolic activity associated with the parasympathetic system. The diencephalic centre is stimulated by sensory impulses from many directions. Insomnia might be due to excessive cortical activity, and for this there is no need to use drugs strong enough to depress the diencephalon.

Others regard sleep as a rhythmic depression of the activity of the brain and insomnia as due to one or a combination of two causes: abnormal afferent stimuli affecting the brain at a time when its depression is due or increased excitability of the brain cells. The rational treatment of the first type is to remove the stimuli if possible. Increased excitability may be congenital or acquired; there are brains which are easily kept awake from childhood. Excitability can be in-

creased artificially, as by caffeine, ephedrine, and high blood pressure. Bromides are especially valuable for normal brains kept awake by such stimuli as worry.

The treatment of insomnia is of importance. Many of the chronic invalidating diseases, such as chronic malaria, kala-azar, ankylostomiasis are accompanied by loss of sleep and the practitioners are confronted with the problem of procuring rest for the body, in addition to finding some specific remedy for the malady. The use of hypnotics is not, however, always indicated and treatment may be described under two heads.

1. **General measures.** For minor ailments, such as flatulence and distension of the stomach no hypnotic drugs are called for, careful regulation of the dietary together with some gastric sedative will relieve the condition and help to produce sleep. In cases where the specific cause of sleeplessness is untraceable, a careful survey has to be made as regards any unusual mental stress or strain which may be responsible for the loss of sleep.

General hygienic measures, regular and careful dieting, exercise in the open air without involving any physical fatigue, will be effective in those cases where insomnia is due to overwork and prolonged mental exertion. A holiday in the country, in the hills, or at the seaside are often the most successful remedy, although some hypnotic may be necessary some time or other to supplement the effect. Besides conditions that favour relaxation, viz., a quiet room, and a suitable bed will be of great help.

2. **Drugs.** Insomnia being a very common complaint, there is a great demand for some safe and reliable hypnotics. There are quite a large number of compounds on the market and they are mostly similar as regards their general property. According to Clark the properties of an ideal hypnotic are:—(1) The drug must produce a reliable hypnotic effect. (2) The hypnotic action must be produced without a preliminary stage of excitement. (3) The drug must not irritate the stomach. (4) The drug must be absorbed readily, so that the hypnotic action is produced at a regular interval after the administration of the drug. (5) The drug must either be broken down in the body or else be excreted rapidly, so that it produces no after effects next day, and does not produce cumulative poisoning when taken daily. (6) The drug must not produce

dangerous side actions, such as cardiac depression. (7) There must be a sufficient margin of safety between the dose required to produce hypnosis and that which produces medullary depression. (8) The drug must not produce tolerance, nor a drug habit, when given regularly over long periods.

There is no drug, which possesses all these qualities together and it is only after prolonged use that some of the disadvantages are found out.

The important thing is to know the cause of insomnia; the cause should be treated, and hypnotics should only be used when general measures fail or are inapplicable. Drugs of low toxicity include the inorganic bromides (*e.g.*, sodium, potassium, ammonium, strontium, and calcium bromides), alcohol, phenazone and its derivatives, aspirin and salicylic acid derivatives. Combinations of these with opium preparations or codeine are often effectual. The great change during recent years has been the production of large numbers of barbituric acid derivatives and the introduction of basal anaesthetics, many of which are being used as hypnotics. Other hypnotic drugs of varying degree of toxicity are the alcohol-chloral group—chloral, chloralamide, chloralose, butyl-chloral, chloretone, hypnal, dormiol, isopral, ural, bromal, amylene hydrate, paraldehyde, aponal, neuronal, hedonal, avertin. The urea group includes urethane, aponal, aleudrin, adalin, bromural, somnosal; and the sulphone group sulphonal, trional, tetroal. Chloral and chloralamide are good hypnotics which have dropped out of use. Avertin (tri-brom-ethyl-alcohol) is as toxic as chloroform. Care and experience are required to decide on suitable doses. The members of the urea group are safe and are not very toxic. The sulphone group is not much used; these drugs are slowly absorbed and there is a danger of cumulative effect.

The barbituric acid group offers a most formidable list of preparations. When a higher allyl group than ethyl is introduced the drug becomes much more toxic. The compounds of these drugs with analgesics are dangerous because of the risk of overdose of hypnotic while a large enough dose of the analgesic is being given. Barbiturics are rapid and certain in their action. They act much more quickly on an empty stomach or if taken with alcohol. Idiosyncrasy to these drugs occurs and might be natural or acquired; any indication of allergy, hyperthyroidism, or latent liver or renal dysfunction is a danger signal. Full doses of a basal anaesthetic are very dangerous in the presence of any of these danger signals, but a smaller dose will produce an adequate effect. Any prolonged toxic condition renders these drugs much more active. They may produce nerve paralysis and after large doses coma may set in. There is not much risk of cumulation, and very little tolerance is as a rule acquired. Habit formation undoubtedly occurs; if they are taken regularly every night it is common for an

overdose to be taken sooner or later. Many cyclical cases get an obsession of insomnia and no drug would put them to sleep.

Analgesics might produce sleep by reducing afferent stimuli and can be usefully combined with hypnotics, but a fixed inflexible combination is dangerous. A small analgesic dose of morphine combined with chloral might be more effective than a large dose of the either drug alone. Combinations of hypnotics acting at different points are also useful. Salicylates have a special property of diminishing painful stimuli and thus act secondarily as hypnotics.

Chloral hydrate. The hypnotic effect is produced with doses of 10-20 grains by the mouth in ten to fifteen minutes' time and sound sleep in an hour. It lasts several hours resembling the normal physiological sleep and the patient can be easily and completely aroused and awaken refreshed without any depressant after-effects. It may also be given per rectum and this method is the only channel of administration in eclampsia, and in convulsions of tetanus where the oral method is impossible and the hypodermic route too irritant to be of practical use. The dangers of depression of the heart and respiration with chloral are over-rated and it can be considered a safe hypnotic if it does not overstep the therapeutic limit.

Butyl chloral hydrate. The hypnotic effect of this drug is of shorter duration and the depressing effect on the heart is more marked. It is said to be particularly useful in facial neuralgia in doses of 5 to 20 grains.

Chloretone. The action is similar to that of chloral hydrate, but it is probably more toxic; it is largely used as a gastric sedative and also to prevent sea-sickness, in doses of 5 to 20 grains.

Chloralamide. This compound is a combination of chloral hydrate with formamide. It is prescribed in doses of 15 to 30 grains but is probably less effective as a hypnotic than chloral hydrate.

Other related compounds such as chloralose, isopral have been prepared. But they appear to have no advantage over chloral hydrate.

Paraldehyde. It produces natural sleep in 15 to 20 minutes lasting for several hours, but the effect of the drug is less certain than chloral hydrate and it has no analgesic action. It is said

to produce no depressing effects on the heart and respiration in therapeutic doses and can, therefore, be safely administered in cases complicated with heart disease. The disadvantages of the drug is that it has got a very unpleasant taste which, however, can be rectified by giving it in some flavouring agent. Prolonged use of paraldehyde leads to irritation of the throat and stomach, an unpleasant odour in the breath, dizziness and faintness, and a habit not unfrequently develops.

The dose of paraldehyde for single administration is one drachm (4 c.cm.) and in some cases two drachms may be given. In cases where the drug has to be given repeatedly, one teaspoonful every hour should be given till sleep is produced.

Sulphone group. Sulphonal is insoluble in water and is absorbed very slowly from the gastro-intestinal tract. Hence there may be delay in producing the desired hypnosis after a dose of sulphonal which must, therefore, be properly timed. The sleep that is produced, lasts for six to eight hours and sometimes the effect may be continued for the next 24 hours. On account of its slow rate of excretion, the drug tends to produce cumulative effects and may give rise to signs of poisoning.

Sulphonal is prescribed in nervous disorders when chloral hydrate is contra-indicated. It is also useful in cases of insanity to control the excitable symptoms. The ordinary dose is 10 to 15 grains (0.75 to 1.0 gm.) and in urgent cases as much as 30 grains (2.0 gm.) may be given preferably in warm milk before bed-time. This drug should never be continued for more than a week at a time as cumulative effect may set in. Trional and Tetronal have been used but have little advantage over sulphonal.

Urea derivatives. Urethane and the other related urea derivatives have very feeble hypnotic action. They are not now used in therapeutics.

Barbituric acid derivatives. Barbital is diethyl barbituric acid or diethyl malonyl urea. It was introduced by Emil Fischer and Von Mering in 1903 under the name of Veronal. Barbital is the chief hypnotic of malonyl urea series, though its introduction was immediately followed by other barbiturates.

Action and uses of barbiturates. The hypnotic and sedative action of the barbiturates is responsible for their extensive use in various ailments to produce calmness and sleep, to suppress convulsions and even to produce partial or complete anaesthesia. With ordinary doses their analgesic effects are not marked but they can be advantageously employed with other analgesic drugs so as to potentiate the action of the latter. If taken on an empty stomach or with alcohol their effect is accelerated. The effect of a dose is prompt, securing dreamless sleep in about half an hour after oral administration, and immediately after intravenous use. The sleep lasts for four to eight hours, varying with the individuals and with the preparation used. The patient generally awakens refreshed, but in some cases there may be a feeling of lassitude, vertigo and headache. Generally there are no undesirable side effects with most of these drugs; only in some cases the duration of narcosis may be prolonged. There is not much risk of accumulation with these drugs, it was not so much the drug itself that accumulated as the effect. There is very little tolerance of these drugs but habit-formation undoubtedly occurs.

The barbiturates, such as barbital and phenobarbital are generally given at bed-time to insure natural sleep. With the other barbiturates the duration of sleep and the after inertia is shorter. These drugs may be administered by all channels, such as by the mouth or the rectum, hypodermically or by the intravenous route. As hypnotics they are probably more effective and somewhat more analgesic than chloral hydrate and the margin between the ordinary therapeutic and toxic dose is considered to be wide enough. The chief conditions for which they are employed are to dull worry and excitement, to calm nervousness and obtain tranquillity and rest. They may, therefore, be used in hyperthyroidism, chorea, hysteria, neurasthenia, in epilepsy in the intervals between the seizures, in mental disturbances and in impending delirium tremens.

Cautions and contraindications: Cases of poisoning from the use of barbituric acid derivatives including barbitone (veronal), medinal, luminal, nembutal, amytal, etc., have been

observed very often and great care should be exercised when prescribing these drugs. The average fatal dose for barbitone is about 50 gr., although death has occurred after such small a dose as 15 grains. There is always danger of cumulative effects and of habit formation when these drugs are taken in therapeutic doses on successive nights. Moreover, in addition to their specific hypnotic action, these drugs also have effects on the lungs, heart and kidneys. Larger doses and in susceptible individuals smaller doses, may cause inflammation of the lungs, while heart failure and even death may sometimes supervene from toxic effect on the myocardium. The kidneys may be injured and suppression of urine may result; this has been observed especially after administration of nembutal.

Certain conditions which greatly modify the action of these drugs should also be borne in mind. Thus the effects of barbituric-acid derivatives are greatly enhanced in hyperthyroidism or when toxæmia is present; an ordinary normal dose may then produce dangerous symptoms. Patients with exophthalmic goitre are very susceptible to nembutal and administration of even 6 gr. doses has been followed by fatal results. These drugs should always be avoided in cases of renal and hepatic insufficiency.

Barbital. The hypnotic action begins in about half an hour apparently with little after-effects and it is considered quite safe. Long-continued use should be deprecated, and in patients with cardio-renal disease it must be given with caution as excretion is delayed.

As a hypnotic veronal is best prescribed in the form of a powder, to be given in hot fluid, such as hot milk, half an hour before bed-time in doses of 5 to 10 grains (0.3 to 0.6 gm.). Ordinarily 5 grains are sufficient to produce sleep and more than 20 grains should not be given in 24 hours. Pills or tablets should be crushed before swallowing to insure absorption.

Veronal sodium. Synonym—*Medinal*. This drug, it is claimed, acts more rapidly on account of its greater solubility. Even small doses, such as 1 grain three times daily, in some cases produce a lengthy sleep. It is stated that toxic symptoms

do not appear with less than 15 grains daily, whilst an adequate sedative effect is obtained with small doses.

Nembutal. Synonym—*Pentobarbital sodium* ; *Sodium iso-amylal*. Its action and uses are essentially similar to those of barbital, but it is effective even in smaller dosage. The action is of relatively brief duration, which is an additional advantage, especially when relatively large doses have to be administered. It is now used exclusively as a sedative, particularly before local, general or spinal anæsthesia and as a hypnotic in various mental disorders. The dose is $1\frac{1}{2}$ grains in capsule by the mouth. In maniacal cases about 3 grains can be given which can be cautiously increased by $1\frac{1}{2}$ grains till the desired effect is produced.

Amytal. The general action and uses of amytal are similar to those of barbital. It is used as a sedative and hypnotic in insomnia and as a preliminary medication to surgical anæsthesia. The sedative dose is $\frac{1}{3}$ to $\frac{3}{4}$ grain (0.02 to 0.04 gm.) twice or thrice daily by the mouth with water or hot milk; as a hypnotic $1\frac{1}{2}$ to 5 grains (0.1 to 0.3 gm.) should be given before bed-time.

The mono-sodium salt of iso-amyl-ethyl-barbituric acid is on the market under the name of *sodium amytal*, and is a sedative hypnotic.

Luminal. Synonym—*Phenobarbital*. Luminal is used as a useful hypnotic in conditions of excitement, in sleeplessness associated with pain, migraine, chorea, neurasthenia, in convulsions of children, in mental conditions and various other disorders. Its chief use is as a sedative and antispasmodic in the treatment of epilepsy, in which it lessens the frequency and severity of seizures. In simple insomnia, $1\frac{1}{2}$ to 5 grains (0.1 to 0.3 gm.) dissolved in hot water are given, and where there is excitement as much as 10 grains may be administered but should be used very cautiously.

Luminal-sodium or phenobarbital sodium is a soluble preparation of luminal and has been used intramuscularly in epilepsy. It has the same action and uses as luminal but it is said to be more efficacious in epilepsy. The drug is best given

in solution with hot milk or water in doses of 1 to 2 grains once a day usually at bed-time.

The disadvantage of luminal and its sodium salt is that they are liable to produce scarlatiniform rashes resembling measles. It has been observed that the effective dose of luminal is very near the toxic dose and continuance of the drug for more than a week may produce toxic symptoms.

Bromides. These are not, strictly speaking, hypnotic drugs, but they depress the motor functions, leading to a condition of dullness and apathy which conduces to sleep and is, therefore, particularly useful in nervous insomnia. The effects are generally different from those of the other hypnotics, the bromides produce a mental calm, progressing to sluggishness, lack of attentive power and muscular weakness. All these dispose towards sleep. If the dose is not excessive, perception, observation, and motor functions are not interfered with, but with excessive doses or after prolonged administration, psychic depression and confusion of speech are evident. As hypnotics bromides of sodium, potassium and ammonia are generally used. They are quite effective in doses of 15 to 30 grains, given one to two hours before retiring. In epilepsy, the bromides prove very successful in quite a large percentage of cases. In most cases the attacks become milder and less frequent, and may be suppressed for the time being. Bromides have, however, little action on pain.

Hyoscine. In cases where insomnia is due to acute mania it is used as a powerful narcotic. It is said to increase the action of the heart and circulation without producing any effect on respiration or causing dryness of the throat. In the dose of as little as $1/480$ grain it produces its brief mydriatic effect within 18 minutes. It should be avoided in glaucoma.

In all cases where there is a condition of cerebral hyperexcitability, *e.g.*, in chorea, diathermasia (thermal stroke) acute mania, delirium, tremors and post encephalitic Parkinsonism, hyoscine is indicated in doses of $1/50$ to $1/200$ grain hypodermically.

Pain and the Use of Analgesics

The commonest and the most important symptom for which medical aid is sought is pain. Pain causes intense suffering and a good deal of exhaustion and is a condition which demands instant relief. It is the sacred duty of the medical profession to try to relieve pain by all the remedial means at their disposal. Attempts have been made for a very long time to find drugs which will relieve pain and lessen the suffering of the patient. Opium, the pain-relieving drug *par excellence*, was discovered years ago but time has shown that there are many limitations to its safe administration. The advance of modern organic chemistry has brought within our reach a host of new synthetic analgesic remedies, which though not as potent as opium derivatives are very useful in a variety of conditions. A short review of these developments should, therefore, be found useful to the practitioners.

The opium alkaloids. Opium contains a large number of alkaloids which belong to two groups. The phenanthrene pyridine group includes morphine, codeine, thebaine, etc., and the benzyl-isoquinoline group comprises narcotine, papaverine, narceine, etc. Morphine is the most important of the opium alkaloids as a hypnotic and analgesic; but it is the most depressant while codeine has a much feeble depressant action, and thebaine is a definite convulsant.

Morphine and opium are used to lessen pain and to procure sleep in all conditions due to pain and disturbing influences. They relieve pain more efficiently than any other drug and is in fact the only remedy available when others fail. The opium alkaloids have been indiscriminately and injudiciously employed in therapeutics. It should be remembered that the relief of symptoms from morphine is only temporary, and persistent use of the drug may do definite harm by obscuring the diagnosis. The danger of habit formation should also be borne in mind and it is in cases of neurotic individuals and in chronic diseases that the habitual use of the drug leads to addiction.

For the relief of pain opium and morphine surpass all other analgesics. For oral use, Tincture of opium (5 to 15 minims) or

Liquid hydrochloride of morphine (10 to 60 minims) can be used. Hydrochloride or sulphate of morphine in doses of $1/8$ to $1/4$ grain hypodermically generally suffices to dull the sensation of pain and produce sleep. Omuopon and alopon are preparations containing all the alkaloids of opium, which can be given either by the mouth or subcutaneously in doses of $1/6$ to $1/3$ grain, and are said to disturb digestion less than morphine alone. In cases of insomnia the use of these drugs should only be advocated when it is due to pain, cough, dyspnoea and other urgent symptoms, the cause of which cannot be controlled immediately. In nervous insomnia and in psychic excitement morphine should not be given. Smaller doses should always be tried and morphine is best combined with atropine ($1/100$ grain) to counteract the depressing effect on the respiratory centre.

Morphine derivatives. A few compounds have been synthesized from morphine with a view to finding a remedy which will produce the therapeutic effects of morphine without having any tendency to respiratory depression or to production of drug-habit. Though a large number of such derivatives have been prepared, in fact no derivative has been found which combines in itself all the advantages of morphine and yet does not share the disadvantages of the latter. Codeine or its salt codeine phosphate, in doses of $1/4$ to 1 grain, is less narcotic, less constipating and is believed to be less liable to produce a habit. Its use is, therefore, steadily increasing. Heroin is diacetyl morphine and resembles morphine in its general action but is more depressant to the respiratory centre. The dose is $1/25$ to $1/8$ grain, and for hypodermic use $1/12$ grain should be given. It shares in fact all the disadvantages of morphine without having any advantages over it. Heroin, however, is such a dangerous drug of addiction that its use should be permitted only under strict medical supervision. Dionin is ethyl morphine and stands intermediate between morphine and codeine. A few oxidation products of morphine have been recently prepared; they are dilaudidide (dihydromorphinone) and dicodide (dihydrocodeinone). They are all habit-forming and have no special advantage. The

following table from Clark (1933) gives the expert report of the League of Nations (1931) about certain morphine derivatives.

Drug	Mean therapeutic dose in grammes	Relative toxicity	Relative power of producing addiction	Relative action as analgesic	Relative depression of respiration and cough	Relative depression of gut movement
Morphine	0.02 gm.	1	1	1	1	1
Codeine	0.04 „	$\frac{1}{2}$	very slight	very slight	$\frac{1}{2}$ to $\frac{1}{3}$	$\frac{1}{2}$
Heroin	0.005 „	5—10	2—4	2	2	very slight
Dicodide	1.005 „	...	$\frac{1}{2}$?	1	?
Dilaudide	9.008 „		$\frac{1}{2}$	1	$\frac{1}{2}$	very slight

Aromatic analgesics. A large number of coal tar derivatives are commonly used to lower temperature and to relieve headache and pain. They have analgesic effect against neuralgic and muscular pains, headache, migraine, cold, etc., but are often ineffective if the pain is due to some injury.

Aspirin (acetyl salicylic acid), is the most popular remedy for headache in doses of 5 to 15 grains. Nothing very definite is known as regards the etiology of headache. A rise in the pressure of the cerebro-spinal fluid is a frequent cause of headache while the spasmodic contraction of the cerebral vessel may probably be responsible for migraine. The manner in which these drugs act is uncertain, and Barbour believes that acetyl-salicylic acid causes a transference of water from tissue into blood and thereby relieves headache. The depressant effect of the drug on the heart precludes its continuous use. Phenazone or antipyrin and phenacetin were formerly used as analgesic to relieve headache, migraine, facial neuralgia, etc., but they are now less frequently used. Pyramidon or amidopyrin acts similarly to phenazone and is effective in doses of 5 to 8 grains. It is an efficient analgesic and its toxicity is very low. Veramon is a combination of amidopyrin with diethyl barbiturate and is said in many cases to relieve pain as well as morphine; Allonal, a combination of allyl isopropyl barbituric acid with amidopyrin has both analgesic and hypnotic effect. Cibalgin, a compound of amidopyrin, with dial, is given in doses of 4 to

16 grains. Compral, a new analgesic, is a combination of pyramidon with trichlorethyl urethane for use in pain generally; one to two tablets of $7\frac{1}{2}$ grains each will be useful.

CHAPTER X

TONICS

The word 'tonic' is commonly used by physicians and by the laity at large to denote remedies which stimulate the protoplasmic activity of the tissues, thereby increasing the general metabolic processes of the body. Tonics are generally employed in conditions of asthenia, neurasthenia and general depression of the body activities after illness, strain and effects of climatic conditions. In tropical climates one frequently meets with cases who are victims of chronic maladies or have become debilitated by living in a hot and damp atmosphere. Good nutritious food and rest, combined with tonic drugs, go a long way towards curing this condition. Tonics produce a sense of well-being, increased strength and vitality by stimulating the functional activity of the digestive organs as well as by improving the general condition of the hæmopoietic system. They contribute towards the improvement of the general tone of the run-down body or some of its component parts. Tonics are, therefore, classed as general tonics, digestive tonics, cardiac tonics, hæmatinics, nervine or nerve tonics and so on. It should be realised, however, that the convalescent from disease improve more by adequate rest, proper selection of nutritious and easily digestible diet and good hygienic surroundings than by tonic drugs alone, which only aid and speed up the process.

GENERAL TONICS

The drugs classed as tonics are very large in number, but here we will only discuss a few of the important ones, whose action can be explained rationally.

Bitters. These are always prescribed to patients convalescing after long protracted illness, where there is a definite derangement of the digestive functions and an upset of the general metabolic processes of the body. They are used to improve the appetite of such patients and are generally given before a meal. They produce a reflex flow of the gastric juice which is bene-

ficial to the impoverished digestive process. The effect of these drugs is never due to direct contact of the drug with the oxyntic cells of the glands in the gastric mucosa, but is entirely reflex through the gustatory nerves. The common bitter substances in use are gentian, quassia and calumba, while many of the bitter alkaloids, such as the cinchona alkaloids and strychnine, are commonly employed for their bitter action in small doses.

The preparations of cinchona and quinine are employed in very small doses to stimulate the gastric mucosa; they thereby increase secretion, improve appetite and aid digestive processes. The infusion of cinchona is an excellent stomachic in cases of mild gastric catarrh and atonic dyspepsia. The compound tincture in combination with *nux vomica* is often used as a general tonic and appetiser. In all post-febrile states, in convalescence from prolonged illness, in general debility and cachexias from various chronic maladies, quinine is often prescribed as a tonic in conjunction with *nux vomica*, iron and arsenic. Though quinine is believed to be a cardiac depressant, the drug in small doses acts as a sedative and by slowing down the pulse improves the irregularity in rhythm and is thus beneficial to the heart.

Strychnine. Preparations of *nux vomica* are often prescribed for their simple bitter action. They always invoke a reflex flow of the gastric juice and tone up the muscular wall of the viscus, thereby improving the appetite and aiding the digestive functions of the patient generally. Strychnine is thus used in atonic dyspepsia and during convalescence from acute illness. Besides its bitter properties, strychnine is often used as a tonic to the nerves and the muscular system. It diminishes the 'synaptic resistance' in the nervous system, whereby a smaller stimulus can pass a greater number of synapses than before and bring into action more nerve fibres. It has, therefore, been used in post-diphtheritic paralysis of muscles and post-operative paralysis of the stomach and gut. It is a good tonic for sexual debility, impotence and spermatorrhoea. Strychnine is often reputed as a cardiac tonic, but views are very conflicting regarding its direct effect on the heart. Experiments show that the drug has no direct effect on an isolated

perfused heart; in fact, it depresses it. It is, however, held that the drug does indirectly improve the heart beat through its stimulating effect on the medullary centres. The drug is undoubtedly an emergent cardiac tonic, as when injected with atropine in threatening cardiac failure, it will almost immediately raise the tone of the organ and strengthen the pulse. Injections of strychnine are useful in weakness of the heart in acute fevers, such as pneumonia, influenza and diphtheria. It is held that the drug increases the blood pressure by its effect on the medullary centres and in this way improves the nutrition of the myocardium by improving the coronary circulation. Strychnine is also a useful respiratory stimulant in chronic bronchitis, pneumonia and emphysema. As a general tonic and stimulant of metabolism, strychnine is unrivalled. As a tonic in cachexia and general debility, it should be given in very small doses. In convalescence from exhausting illness associated with anæmia, strychnine is invaluable as a general tonic and hæmatinic in combination with iron and arsenic. Strychnine is a tonic in the real sense of the word, in that it increases the tone of all stripped and unstripped muscle tissue in the body which is lowered after disease and other debilitating conditions.

Alcohol. It has long enjoyed the reputation of being a good tonic. It is often used in cases of chronic debility and various wasting diseases. It has been shown that regular use of moderate doses of alcohol with meals promotes digestion, increases appetite, checks waste, favours deposition of fat and so alcohol practically possesses all the properties of a true food. It is a food in the sense that it is readily oxidised, yielding considerable energy, which is only available for immediate emergency use and cannot be stored as a reserve for future use.

Alcohol excites a psychic secretion of gastric juice and it can also produce a direct stimulant action on the fundus of the stomach, causing an abundant secretion of dilute gastric juice. Apart from being a digestive stimulant, it is also used as a restorative tonic in urgent cases of fainting or threatening cardiac failure due to shock, hæmorrhage, etc. Here it acts as a diffusible stimulant reflexly and thereby increases the pulse rate, blood pressure and respiration.

Alcohol is contained in various tonic wines sold in the market and is often prescribed for convalescing patients. It should always be given in small and frequently repeated doses even in health, as given in this way, it is completely metabolised. If larger quantities of alcohol are taken, its toxic effect over-balance any of the beneficial effects produced.

Thyroid. The use of endocrines as tonics is of very recent origin. They appear to form a system which regulates the rate of metabolism, and the growth and development of the body. Thyroid is reputed to be the most powerful tonic of all the endocrine glands. It has been considered as the trigger gland of the body, which sets other endocrines to action. Besides its use in thyroid deficiency diseases, it is often prescribed as a tonic to neurasthenic patients, suffering from general prostration and in whom energy and appetite are lacking. It is invaluable to convalescing patients and to fatigued subjects after long-continued strain and over-work. In tropics, due to the enervating influence of the climate, such cases are frequently met with and the drug in small doses has given most encouraging results. It acts by increasing the rate at which energy is produced by the body. Administration of thyroid adds more fuel to the fire of metabolism in the body and the oxygen intake rises. The body-machine is geared at a higher level, and food normally used to supply the current demand for energy and stored as fat, is now used to yield more energy and only a small proportion is reserved for future use. Appetite is thus increased, patients feel more energetic and the gland now serves the purpose of a tonic in the right sense of the word. The drug should be prescribed in doses of $\frac{1}{2}$ to 1 grain twice daily for this purpose for a period not exceeding a fortnight at a time.

Arsenic. The drug is a true digestive tonic and when given in small doses ($\frac{1}{50}$ gr.) it acts as a stomachic by its local action on the gastric mucosa. When given before meals it stimulates appetite and aids digestion by increasing the activity of salivary, peptic and intestinal glands. Medicinal doses improve local circulation and nutrition of the tissues and increase deposit of adipose tissue. As a general tonic in com-

bination with strychnine, it is of value in depressive psychoses of old age, and those that follow acute infections, such as influenza and typhoid fevers, in neurasthenia, hypochondria and melancholia and in cachexias of maladies like chronic malaria, syphilis, etc.

Calcium. Calcium compounds have a great reputation as tonics. Calcium is a normal constituent of the body tissues and is indispensable to the life of all organisms. The calcium content of the body is about 2 per cent. of its entire weight. The nerve and muscle cells require an optimum concentration of calcium for their proper functioning, and so calcium is the best tonic for the neuromuscular mechanism of the body. The compounds of calcium promote nutrition, improve cardiac and vascular tone. In pulmonary tuberculosis, where the excretion of calcium is excessive, a prompt and adequate supply of the drug is essential and favours the process of healing of tubercular lesions. Calcium lactophosphate and glycerophosphate with cod-liver oil and ultra-violet therapy are very useful in rickets and malnutrition. Marked improvement is noticed in secondary anæmias with combined therapy of calcium, iron and arsenic. Calcium should always be given along with parathyroid for its efficient assimilation in the body and can be prescribed with advantage in all conditions of debility where the body metabolism is distinctly sluggish.

Iron. Iron is a general tonic and a hæmatinic. It is a natural constituent of the body and is a food; the amount of iron necessary to keep a person in normal health is 1/11 to 1/8 gr. daily. The tone of the nervous system is improved with iron therapy in cases of mental overwork, neurasthenia and neuralgia, because it stimulates the body metabolism. In combination with arsenic, strychnine and quinine, it is prescribed with benefit in all forms of debility with or without anæmia, and where there is a general lack of tone in the tissues. In all conditions where there is loss of appetite and sluggishness of body functions, iron therapy is beneficial. The importance of iron as a hæmatinic has been dealt with under anæmia.

Phosphorus. Phosphorus is the normal constituent of most tissues and it exerts a stimulating influence, when administered in small doses, upon their nutrition. This is most marked as regards the nervous and the osseous system. Phosphorus has been regarded as a useful tonic and restorative in neurasthenia or nervous debility, when the system is weakened by anxiety, overwork or sexual excesses. In anæmia, in combination with iron, small doses are said to be beneficial. Phosphorus is recommended as a restorative after typhoid fever, as it is believed to hasten the convalescence. In cases of chronic malaria, phosphorated oil is considered to be of value. During medication by phosphorus, the patient should be watched for the first symptom of overdose. The drug should never be given in large doses and is not indicated where acute or inflammatory lesions are present. It should be given in form of alcoholic or oily solution.

Phosphoric and hypophosphorus acids and their preparations are also useful as general tonic. It is stated that the morbid conditions in which these are most beneficial, are those in which there is demineralisation of the organism with hypo-acidity of the urine. The lactophosphates and hypophosphites are simply convenient modes of administering calcium, potassium and other substances, while phosphorus acts as a stimulant to bone growth and not by its deposition in the bone. This difference between these salts and phosphorus should be clearly borne in mind.

CARDIAC TONICS

Physiological considerations. The circulatory system with the lungs may be regarded as a single functional system, which supplies oxygen to the tissues and removes carbon dioxide from them. They are efficiently controlled according to the needs of the body from time to time by a central and a local mechanism. The heart forms the central and the most important organ in the system and continues functioning regularly and efficiently throughout life without ever resting. Normally, in a healthy adult, it makes on an average about 103,680 contractions a day, though these considerably vary in different stages of life and in diseases. The capacity of muscular exertion of an

individual in health and the fate of the patient in disease, all depend on the condition of the heart. The heart is characterised by its unique properties—namely, automaticity or stimulus production, rhythmicity, excitability, contractility, tonicity and conductivity.

Various theories have been advanced to explain the origin of heart beat. It is regarded that the initial stimulus leading to heart's contraction is inherent in the specialised contractile cardiac tissue as is evidenced by the fact that heart starts beating in the foetus, *in utero* even before the development of the nervous system. Embryologists hold that it is the primitive embryonic tissue in the pace maker of the heart that is responsible for the origination of the initial beat of the heart. The heart beat originating in the sino-auricular node, situated at the junction of the great veins at the base of the heart, passes as a wave of contraction over the musculature of the auricles. It then reaches the auriculoventricular node, where a little delay occurs, but thence the wave rapidly passes along the specialised conductive tissue, namely, the bundle of His and the Purkinje system. The wave of excitation is accompanied by a change in electric potential, which can be demonstrated by the string galvanometer. The interval between the commencement of the auricular and ventricular contraction is about 0.15 second. The contraction of the heart is then followed by an absolute refractory period, during which the cardiac muscle is incapable of further excitation. The heart recovers its power of excitability earlier than the contractility and the duration of the refractory period depends on the period of rest. The force of contraction of cardiac muscle and its oxygen consumption depend on the initial length of the muscle fibres. The efficient and a powerful contraction of the left ventricle of the heart depends on an adequate inflow of the venous blood into the right auricle. Any increase in the amount of venous inflow will distend the chamber of the heart more and consequently will increase the oxygen consumption required to supply the energy for doing the extra work as a pump to maintain an efficient circulation for the body tissues. The heart has the first call of blood leaving it by the aorta and as much as 20 per cent. of the total output may enter the coronary circulation. Unlike voluntary muscles, heart can never enter into oxygen debt. Hence a deficiency in oxygen supply to its need will result in an accumulation of lactic acid definitely depressing and injuring the efficacy of this vital organ. A deficient coronary circulation will impoverish heart from lack of proper nutrition and the whole body will share the misery.

The heart has great reserve power to meet the demands of emergencies and utilises only a fraction of it for its work, when the body is at complete rest. It has been found that the oxygen consumption during complete bodily rest is $\frac{1}{4}$ litre per minute, a heavy meal

increases to $\frac{1}{2}$ litre a minute and walking at the rate of three miles an hour increases it to 1 litre. An athlete with a large heart has immense reserve powers, his pulse rate is slow at rest, but the stroke volume of the heart is great, and hence the circulation volume is sufficient to meet the requirements of the body tissues. The reverse is the case with a non-athlete with a small heart. His reserve power is small and is rapidly and easily exhausted after moderate exercise as manifested by the signs and symptoms of loss of compensation. Even in some pathological hearts, the compensation is not lost, and the heart can still supply the oxygen needs of the body at rest. Clark states that in failure of the vasomotor mechanism, some injury to the cardiac valves, poisoning of the cardiac musculature and disordered cardiac rhythm are the possible factors responsible for failure of circulation. In shock and other allied conditions, the capillaries lose tone due to paralysis by some toxin or local metabolites resulting in stasis of the blood in the capillary bed. The venous inflow and the filling of the heart become deficient, the organ beats strongly to compensate the situation but with no effect, the coronary circulation suffers, the heart lacks nutrition and ultimately a vicious circle is established, in which the whole system partakes.

The action of the heart is also regulated by two sets of nerves, namely, the sympathetic and the vagus. The sympathetic is the augmentor nerve of the heart, it increases the force of contraction of both the auricles and the ventricles, and the rate of conduction from auricle to ventricle. The vagus is the inhibitor nerve of the heart, it slows the heart, depresses the force of beat of the auricles and also the rate of conduction from the auricle to the ventricle. The vagus has a constant control over the activity of the heart; the control is slight at two extremes of life and maximum in early adult life. The vagus also constricts the coronary arteries and the sympathetic dilates them. In spite of the regular and constant nervous control over the heart's activities, the pace maker of heart has a natural rhythm, irrespective of any nervous control.

The demand of the tissues for oxygen varies from minute to minute, and this is regulated by the blood flowing through the small arteries and the arterioles. The distribution of the blood is so efficiently made that the organs, whose continuous activity is most essential to the maintenance of life, receive the major share most promptly and regularly. The central nervous system deserves a foremost mention. Arrest of circulation in the brain only for a few seconds will result in unconsciousness. The brain regulates the general supply of the blood to other organs after ensuring a rich supply for itself. The body mechanism is so adjusted that the demand for blood supply is met in emergent cases for some particular functioning organ at the expense of the other. This is met with by a proper regulation of the arterioles

mostly by a central and a peripheral mechanism. The arterioles are very richly supplied with vasoconstrictor nerves and by their action as well as by the vagal and vasomotor centres in the medulla, the general blood pressure and the supply of blood to different organs of the body are determined. The arterioles supplying the most vital organs of the body, the constant activity of which is most essential to life, are not supplied by the vasoconstrictor nerves. The velocity and pressure in the blood vessels decrease as they branch and become smaller, but remain considerable as far as the arterioles. The arterioles terminate in thin-walled capillaries, which perform rhythmic contractions. At rest, only a small number of them dilate to carry on the circulation to distant parts, while when an organ functionates, the arterioles supplying it dilate and a greater number of capillaries open, and the blood flow to the organ increases manifold. The normal circulation of the blood depends on the maintenance of a certain amount of tone in the capillaries and the veins, failing which the blood stagnates and the heart does not receive adequate quantity of blood to contract upon and to carry on its proper function.

The splanchnic vessels are richly furnished with vasoconstrictor nerves, and next come those supplying the skin and the muscles. It is stated that the blood flow through the skin and muscles at rest is 12-10 c.cm. per 100 grm. per minute, liver and kidney 70 c.cm., brain 150 c.cm. and the endocrines 600 c.cm.

Heart-failure

The failure of the heart to maintain an efficient circulation in the body is not an uncommon complication in diseases. A knowledge of the remedial measures for the maintenance of the heart's action will, therefore, be very useful to the physician practising in the tropics.

From the clinical point of view the following types of cardiac failures are met with:

(1) Acute cardiac failure causing sudden death; it occurs in angina pectoris, ventricular fibrillation and coronary disease. Acute failure is also produced by chloroform, lightning or electrical shock.

(2) Sub-acute cardiac failure occurs in acute infectious diseases, e.g., pneumonia, typhoid, diphtheria, influenza, etc.

(3) Chronic cardiac failure usually occurs in chronic valvular disease and myocardial lesions.

In considering the treatment of heart-failure it should be remembered that the essential cause of heart-failure lies in the heart muscle. The physician should, therefore, focus his attention on it with a view to avoiding further embarrassment of the heart, and in order to promote the efficiency of the myocardium.

The treatment of heart-failure may be conveniently described under the following heads:

General management. When the heart is compensated, careful instructions should be given to the patient regarding his mode of life. It is of vital importance that he should have abundance of physical and mental rest in his daily life. Excitement, anxiety, worry and emotional strain should, as far as possible, be avoided. He should not have any physical exertion that would give rise to breathlessness, palpitation, fatigue, a sense of tightness across the chest, or precordial pain. At the same time a certain amount of graduated exercise is desirable. Walking on the plains is preferable to hill-climbing. When the cardiac affection is progressive, the amount of exertion must be correspondingly reduced. With regard to diet, the food should be nutritious, easily assimilable and not likely to cause indigestion. The fluid intake should be restricted. A carbohydrate diet is bulky and apt to cause flatulence, while a high protein diet increases the resistance in the peripheral circulation. The diet should, therefore, be a mixed one with predominance of the albuminous element. A careful search should be made for a septic focus, which should, if possible, be eradicated. The bowels should be kept open and regular.

Drugs. The underlying idea of treatment with drugs should be, (a) to give rest to the heart as much as possible, (b) to improve the nutrition of the heart and thereby enable it to do more useful work, (c) to increase the force of systole and prolong diastole, thus improving the efficiency of the contractions and lengthening the period of rest. There is a great deal of confusion as to what drugs should be classed as true tonics to the heart. The word 'cardiac tonic' usually conveys the suggestion that an increased activity or tone is being brought on slowly, but which is more enduring, while 'cardiac

stimulant' means a prompt but transient increase in the activity of the heart which is not enduring. Gunn (1928) suggests three possible definitions for those drugs which are used to combat failing circulation. "Firstly, a drug may directly or indirectly increase the output of the heart and under this most of the cardiac tonics are included. Secondly, drugs may increase the 'minute output' by some action on the heart or its nerve supply, and under this may be included such drugs as adrenalin, ephedrine, atropine, ammonia, etc. Lastly, there is a class of drugs which will be regarded as true stimulants, if they produce an increased ventricular pressure by a primary effect on the heart operating under the constant dynamic condition." It should be borne in mind that the idea of treatment of heart-disease is not to increase the frequency of a failing heart, because thereby the process of exhaustion is hastened.

During the compensated stage, no cardiac tonics are required. Tonics, such as iron, arsenic and phosphorus, may be taken from time to time; while in children, cod-liver oil, the syrup of iodide of iron are of special advantage.

Digitalis. The most useful drug for failing compensation is digitalis. In the words of Mackenzie, "Digitalis, acting on the vagus, pulls the reins of the heart, acting on the heart muscle it is a most useful whip, at the same time providing it with food by improving the circulation. By slowing the heart it makes it regular and also this gives the heart an opportunity of resting, so secondarily improving the contractility, conductivity and excitability of the organ."

Lewis writes, "The giving of digitalis to unselected heart cases is much to be deplored. Those who regard digitalis as a cardiac stimulant, mistake its character; its chief action is to rest the heart. To the heart, foxglove is not tonic, but powerfully hypnotic. It controls the diastole of the heart: it extends the period of ventricular sleep."

There are two conditions in which digitalis is indicated: (1) Heart-failure, specially of the congestive type, with cardiac dilatation, diminished contractility and tonicity of the heart muscle, anuria and anasarca. Mitral cases, with waterlogging, and cases of auricular fibrillation, with a ventricular

rate exceeding 80 per minute, react better than aortic cases. (2) Presence of a chronic auricular fibrillation with tachycardia, where heart-failure has not supervened. Such cases may be kept going and heart-failure postponed indefinitely by adequate digitalis medication directed to maintain the ventricular rate below 80 per minute at rest. Provided congestive heart-failure is present, hypertension and aortic regurgitation are not contraindications, as was formerly taught. The results, however, in the above two conditions, as well as in agina pectoris, are not always as favourable as in the mitral group.

Patients put on digitalis for the first time, should go to bed and remain there until the reaction to the drug has been investigated fully. As a routine, the tincture of digitalis, biologically standardized, should be used. A usual and safe dosage for an adult is 60 minims of the tincture daily, by mouth. This may be given divided into two or three doses, diluted with water, and not mixed with other medicines. A daily dose of one fluid drachm meets the requirements of most cases and, for the busy practitioner is simple to calculate and remember.

According to Eggleston the average amount of the drug required to digitalise the human heart is $9/40$ grain of the powdered digitalis or $2\frac{1}{4}$ minims of the tincture per pound body weight. In estimating the weight, the amount of fat and œdema must not be taken into account. In non-urgent cases, one-fourth of the calculated dose is given at once, one-fourth after six hours, and thereafter one-tenth to one-eighth of the total every six hours. But in urgent cases, one-third to one-half is given at once, six hours later one-fifth to one-fourth and after another six hours one-eighth to one-sixth.

The Eggleston method of heavy dosage and rapid digitalization is reserved for the cases 'in extremis' and should be adopted only where the patient can be examined at least twice every day. Ordinarily, the daily dose of 60 minims of the standardized tincture should be continued until either the desired slowing of the heart rate is obtained, or, until nausea or diarrhoea appears.

In Europe and U.S.A., on the average, a total dose of about 7 fluid drachms in 7 days is required to get the reaction. In India, however, the required dose is very much higher due to rapid deterioration and loss of potency of the drug in the tropics. Bose (1925) concluded: (i) The total quantity of the active standardised tincture of digitalis required exceeds 14 drachms given in 14 days: that is, more than twice the dose must be given in India to obtain results. (ii) To obtain prompt results, this tincture should be used in doses of 2 or 3 drachms per day for 5 days. (iii) Heart-failure with normal rhythm requires the same high dosage as with auricular fibrillation, and the response to digitalis is good. (iv) The stage of optimum benefit with digitalis nearly merges into the stage of minor intoxication. (v) With a good tincture, a dose of 30 minims a day can be given indefinitely without toxic effects, because the same amount is daily used up in the body. (vi) Apart from the typical slowing of the heart rate and coupled beats, digitalis may, at times, provoke a sudden regular paroxysmal tachycardia of 180 beats per minute, which is dangerous to a failing heart. (vii) In Europe, more than 50 per cent. of all cases of heart-failure have auricular fibrillation; in India, however, the incidence of auricular fibrillation is about 10 per cent. only, or less.

In recent years *Digitalis lanata* has come into use. It is a potent source of glucosides, stated to be nearly 4 times as potent as *D. purpurea*. *D. lanata* contains four glucosides, of which the chief is *lanadigin*. It is only one-third as toxic as strophanthin; it accumulates in the body more than strophanthin, but much less than the *purpurea* glucosides. Clinically, it is said to act more rapidly than any of the *purpurea* preparations, and the nature of action is similar.

Recently, Bose has worked out the total dose required to produce the digitalis reaction, with the various tinctures, on the basis of one fluid drachm a day. *Digitifortis* (P. D. & Co.) is the most potent of all, being 150 per cent. the standard laid down in the British Pharmacopœia, and one obtains a reaction with six drachms in six days. *Digitutin* (B. W. & Co.) and *Pandigal* (Biersdorf) require a dose of 9 drachms in 9 days, and are weaker preparations, but they are well tolerated in toxic gastritis. For intravenous medication, *Digoxin* (B. W. & Co.) is the most powerful, but *pandigal* and *nativelles digitalin ampoules* are also useful; they are less

dangerous than strophanthin intravenously and in febrile and toxic hearts, are equally beneficial.

Strophanthin. Strophanthin has the same action as digitalis, the standard tincture (dose 2 to 5 min.) acts in $\frac{1}{2}$ to 1 hour, but the effects are unreliable and it is often ill-tolerated. Strophanthin 1/250 grain intravenously is generally given in heart-failure to obtain immediate results. Caution has, however, to be exercised, as the drug sometimes behaves in an unaccountable manner, loss of consciousness has followed an ordinary dose in a weakened patient. It should always be well diluted with 10 c.cm. of normal saline, and injected, very slowly, into the vein. In acute febrile heart-failure, sudden death has rarely occurred with intravenous strophanthin.

Camphor and its derivatives. Camphor is now-a-days largely used in the treatment of heart-failure, especially in chronic myocarditis with simple cardiac insufficiency. In typhoid and pneumonia it is considered as a valuable stimulant to the heart. With regard to its effect on the heart, no decisive and accepted proof has been obtained of any direct action on the organ. Given subcutaneously, camphor acts as a local irritant and reflexly stimulates the medullary centres. The evidence available suggests that it does not directly stimulate the heart, but like alcohol causes redistribution of the blood, which will benefit the patient generally and the heart-beat particularly. It is now generally employed in doses of one to one and a half grains, dissolved in 1 c.cm. of ether or olive oil, and injected hypodermically.

Among other camphor preparations 'coramine' has been given in shock and cardiac weakness resulting from infectious diseases. It has a stimulating action on the central nervous system and on the circulatory and respiratory apparatus. By the mouth 1 to 2 c.cm. of the liquid may be administered and 1 c.cm. of the ampoules may be given hypodermically, intramuscularly or intravenously, according to the gravity of the situation. Cardiazol (Metrazol, pentamethylene tetrazol) is another general circulatory tonic acting similarly. Tablets, 0.1 gm., may be given by mouth or 1 c.cm. of solution in ampoules may be given subcutaneously, 3 to 4 times daily.

Caffeine. Caffeine is a direct cardiac stimulant acting on the excito-motor area of the heart. It produces an increase of the pulse rate, but from the point of view of rational treatment, stimulation of the heart alone will be of little value unless the circulation is improved as well; its efficacy is, therefore, doubted. Caffeine sodium salicylate or caffeine sodium benzoate in doses of 2 grains may be injected subcutaneously to produce stimulation of the heart. But this action is of relatively little value, because in a failing heart, the increase in frequency, leads to exhaustion.

Adrenalin. It is a peripheral sympathetic stimulant. It augments and accelerates the cardiac beats and is one of the most potent therapeutic agents to resuscitate a failing heart. The action and uses of adrenalin are so well known that it is unnecessary to consider them in detail, but there are a few points about its clinical use that are not well appreciated. Adrenalin, when given hypodermically or intravenously, especially by the latter route, causes vaso-constriction and raises the blood pressure, and consequently in damaged myocardium it may throw a sudden heavy strain on the heart and thereby do positive harm. The action of adrenalin is transient and, except in conditions where there is low blood pressure with feeble heart-beat, no permanent improvement in circulation is brought about. It has, however, been used repeatedly and often with success, in threatened or complete arrest of the heart, when that is not due to fibrillation. Intravenously, adrenalin acts almost immediately. The dose should be about one-fiftieth of that of the hypodermic dose, and there is no remedy available that bears comparison with it in such cases. Intracardiac adrenalin to resuscitate the patient in cases of arrested heart-beat or in anæsthetic syncope, has been useful in many instances. The dose of adrenaline by the subcutaneous route is $\frac{1}{4}$ c.cm. or less. Dr. Hurst, of Guy's Hospital, states that 3 to 5 minims is the optimum and effective dose even in severe spasms of asthma. Hurst finds that dose higher than $\frac{1}{4}$ c.cm. causes shock, rigor, and profound bodily tremors and depression for many hours after. For intravenous purposes, a dose

of 2 minims diluted with 2 c.cm. of distilled water, is given very slowly.

Adrenalin is very unstable in neutral or alkaline solutions and in such solutions it is very readily oxidised to form inert substances. The solution turns brownish with age and the deterioration in potency is proportional to the discoloration and any solution thus discoloured is unsuitable for use.

Ephedrine. The vaso-pressor effect of this drug is now well recognised. It is used by some clinicians to guard against heart-failure in pneumonia and influenza; $\frac{1}{4}$ to $\frac{1}{2}$ grain three times daily is effective in cases of low blood pressure. The advantages of ephedrine over adrenalin are that it can be given by the mouth and produces an action of much longer duration. The toxic effects of the drug should, however, be borne in mind.

The author has shown that pseudo-ephedrine has a direct stimulant action on the myocardium. A tincture made from ephedra, which contains both ephedrine and pseudo-ephedrine, has been used with success in epidemic dropsy, pneumonia, diphtheria, etc.; the usual dose is 15 to 20 mins. thrice daily.

Quinidine. The physiological action of quinidine has been fully discussed under cinchona alkaloids. It has been employed in the treatment of persistent auricular fibrillation and flutter and also in paroxysmal tachycardia, in the intervals between the attacks. According to Lewis, it diminishes the sino-auricular rate, increases the refractory period of the auricular muscle and diminishes the rate of conduction of impulses along the A. V. bundle. General toxic symptoms, cardiac failure and embolism may occur during the administration of quinidine. Quinidine is contra-indicated in: (1) quinidine susceptibility, (2) arteriosclerosis, (3) failure of compensation, (4) cardiac dilatation and hypertrophy, (5) marked valvular disease, (6) a history of embolism, (7) heart block and (8) endocarditis.

A preliminary course of rest and of digitalis is advisable before administering quinidine. To obtain an effect on the heart the continued presence of the drug is necessary, and it should be given frequently. An average scheme for administration would be:—A test dose of 0.2 gm. (3 grains) is given and repeated in two hours. If there is no susceptibility to the drug,

begin the next morning with 0.2 gm. (3 grains) four to six times a day. If there is no effect in three days, the dose is raised. If the normal rhythm has not been restored by the end of the week, the drug will probably not prove successful. In some cases the test dose alone may bring the normal rhythm. If successful, the dosage should be gradually reduced and the patient kept on a daily maintenance dose for some time. The drug is usually given by mouth in capsules.

Glucose. It is a valuable agent in heart-failure. When given intravenously, after leeching or venesection, it acts as a food to the heart and stimulates the function of the kidneys. The details of therapy are given elsewhere.

Cane-sugar is considered to be a valuable cardiac nutrient. In the body, it is first converted into glycogen and thence to glucose, and as such serves as a source of food for the heart muscle in conditions of prolonged strain in some acute fevers, as pneumonia, influenza, typhoid as well as in cases of chronic cardiac failure. It is invaluable as a stimulant of body metabolism in various other morbid conditions, anaemia, a-dynamic varieties of rheumatism and in neurasthenic manifestations of the neurotics, where the metabolic processes of the body are depressed. The average adult dose for the sugar is 4-8 ounces a day.

Oxygen. It has been found very useful in cardiac disorders with hypertension, arteriosclerosis, aortic insufficiency, etc. It is administered in form of oxygen bath, 90° to 95°F. (32°—35°C). It lowers the blood pressure, and there is a coincident diminution in the size of the heart. These effects persist only a few hours after the first bath, but after 15 to 20 baths, very prolonged and even permanent physiological and therapeutic effects are obtained. They are contra-indicated where the blood pressure is much below normal, especially if associated with mitral defect and profound anaemia.

Morphine. In nocturnal dyspnoea in cardiac decompensation, morphine is given in sufficient doses to allow the patient to be comfortable. The resulting absolute bodily rest is a prerequisite to the effectiveness of cardiac stimulants. No other

remedy will thus alter the entire clinical picture of a dying case in a short space of time.

There are but two contra-indications to the administration of morphine: (1) Progressive failure of the respiratory centre, (2) Suffocative oedema of the lungs with purulent bronchitis.

Kidney disease is no bar to morphia, because mania, delirium and even convulsions of uræmic origin are often markedly relieved by morphine. Rarely, morphia may induce some cyanosis, but this is readily counteracted by the liberal and continuous inhalation of oxygen by a nasal catheter passed well back into the posterior nares. In fact, in the sudden crises of coronary thrombosis, morphia and oxygen are the two potent remedies, best administered simultaneously.

PART II

HELMINTHIC DISEASES

CHAPTER I

GENERAL CONSIDERATION

Worms are the oldest recognised parasitic organisms which have seriously affected both man and domestic animals. From time immemorial, therefore, attempts have been made to eradicate them from the body by means of different drugs. In spite of this fact it is only lately that the study of anthelmintic drugs has been taken up on scientific lines. In view of the fact that a very high proportion of the human race and a still higher proportion of domestic animals suffer from parasitic infections, particularly in the tropics, and that many of these infections are often severely injurious to the host, much attention has lately been paid to this subject and a great advance has been made in this important field of therapeutics. In the past it has been taken for granted that because a remedy is active against one species of parasite it will be efficacious against others also. These parasites, however, belong to several widely separated zoological groups and differ greatly in their anatomy, physiology, habits and habitat. It is not reasonable, therefore, to expect that any one drug will be effective in anything like an equal degree against such widely different organisms. From the therapeutic point of view parasitic worms may be divided into two main groups.

(1) **Those which live in the gastro-intestinal tract.** Here it is desirable to give drugs which are absorbed as little as possible from the gut, thus ensuring their contact with the

For detailed information on this subject the reader is referred to "Anthelmintics and their uses" by Chopra and Chandler, 1928, from which this section is largely extracted by kind permission of the publishers, Messrs. William and Wilkins Co., Baltimore.

parasites in maximum concentration and at the same time exerting a minimum effect on the host. The drugs are given by the mouth and recently some have been introduced directly into the duodenum. Hookworms, roundworms (*ascaris*), and intestinal flukes are fairly susceptible to these drugs; tapeworms are moderately susceptible, and oxyuris, *strongyloides*, *trichostrongylus*, *trichuris* and others still hold out to a large extent against all efforts to dislodge them.

(2) **Those which live in the tissues of the body and cause somatic infections.** For these extra-intestinal parasites, readily absorbable drugs are given which are more toxic to the parasites than to the host. These drugs may be given by the mouth but are often administered by subcutaneous, intramuscular or intravenous injection. It is only in recent years that any headway has been made against such somatic infections and fairly effective remedies have been discovered for schistosomes, liver flukes, etc.

The word anthelmintic is derived from *anti*—against, and *helminthos*—worm; it is commonly applied to those drugs which expel worms from the gut but anthelmintics may be used against worms in the liver, bladder, connective tissue, etc. These remedies have been commonly but inaccurately divided into *vermicides* (*vermes cæders*) and *vermifuges* (*vermes fugare*). There is, however, no sharp line dividing vermicial and vermifugal drugs, as very often the same drug may have a vermicial and a vermifugal action according to the dose in which it is given. Some drugs such as santonin have an entirely vermifugal action as the parasites are expelled alive, while others like chenopodium are vermicial. Male fern is classed as a vermicide though the tapeworms expelled are often alive.

The qualifications requisite for an ideal anthelmintic are:

(1) It should be safe for the patient. It should be borne in mind that anthelmintic drugs, in general, are not toxic specifically to the worms alone, but in a greater or lesser degree, to all living cells; they may even be dangerous to the host. It is, therefore, advisable that a proper diagnosis be

made by microscopic examinations of the stool, urine, blood, etc., before they are prescribed.

(2) It should be effective in removing the particular kinds of parasites for which it is given. This depends on several factors such as location and species of parasite, the choice, dosage and purity of the drug used, the preliminary preparation of the patient, administration of a post-purgative, dietary measures, etc. In spite of every precaution there are no anthelmintic drugs which have a 100 per cent. efficacy in safe doses for any species of parasites. Fortunately it is not essential to remove all the parasites as unlike bacteria or protozoa, they do not, as a rule, multiply rapidly in the body. Expulsion of the majority of worms is usually sufficient to render the infection innocuous. It is well known that hook-worm infection is practically universally present all over India but the incidence of parasites in certain parts is so low that no untoward effects are produced.

(3) Simplicity of administration. This is of little consequence in the treatment of individual cases, but when treatment has to be carried out in large labour forces it is of great importance, as it not only saves time and trouble but also expense.

(4) The treatment should not be unpleasant and it should have as little after effects as possible. This is of importance when treating labour forces, as labourers will not take a drug with an unpleasant taste or one which produces disagreeable effects.

5. The cost of the drug should not be high. No expensive preparation will succeed for use on a large scale as an anthelmintic, however effective it may be.

Method of administration. All drugs belonging to this group are toxic not only to the parasites, but to the host also. Certain precautions regarding diet, dosage and prevention of absorption of the drug are necessary to minimise toxic effects. Anthelmintic treatment consists of three stages:—

(1) **The preparation of the patient.** In the old days starvation of the patient and a preliminary purgative were considered essential, the idea being to get the alimentary canal as empty as possible so that the drug could come into intimate

contact with the parasites. Starvation has, however, a weakening effect on the patient and renders him more susceptible to the toxic action of the drugs; further, absorption is increased from the empty intestines. A liquid diet for 24 to 48 hours before treatment is usually preferred with a saline purgative the night before. The withholding of solid food leaves the intestine comparatively empty, so that the drug is less diluted and the preliminary purgative helps to clear away the coat of mucus which covers the parasites. The drug thus comes in contact with the parasites in as high a concentration as possible. Some of the recently introduced anthelmintic drugs, such as chenopodium and carbon tetrachloride, are not only quite as effective when given without preliminary starvation and purging, but preliminary fasting and purging considerably enhances their toxicity for the host. With most anthelmintics, except those used against the tapeworm, a light meal at noon on the day preceding the treatment, followed by a liquid diet consisting of milk or broth in the evening, a purgative at bed time and administration of the drug in the morning before any food is taken are all that is required. For tapeworm infection it is necessary that the drug should come into contact with the heads of the worms, otherwise the main body of the parasite is likely to break off leaving the head intact and in a few weeks the whole chain of segments is regenerated. The preliminary preparation is, therefore, essential here. Even with the most careful preparation the best remedies give only about 50 per cent. of cures and without preparation the hope of success is much reduced. *Strongyloides* or *trichostrongylus* are also deeply imbedded in the intestinal wall and the preparation for treatment of these infections has to be very thorough.

Absorbable fats are contraindicated with most of the anthelmintics used against the intestinal parasites, as their presence in the gut leads to absorption of these drugs. Many of the anthelmintic drugs, *e.g.*, carbon tetrachloride, thymol, are soluble in alcohol and its presence in the gastro-intestinal tract is liable to increase their absorption, thus producing toxic effects. It is best, therefore, to forbid its use. For remedies which act upon the liver (*e.g.*, carbon tetrachloride)

if this organ is well stocked with glycogen, it is relatively resistant and, therefore, a rich carbohydrate diet is indicated. In the case of drugs which are poisonous but very insoluble in water, *e.g.*, thymol, the amount of water consumed should be cut down to minimum to prevent their solution and absorption. On the other hand, with drugs which are largely absorbed, and excreted by the kidneys, *e.g.*, beta-naphthol, plenty of water should be given.

A limitation of protein diet is said to be harmful to the parasites. Some foods irritate the parasites but this hardly amounts to anthelmintic action. Mechanical irritation with fibrous vegetables, seeds of figs, strawberries, etc., and the husks of grain are said to have unfavourable effect on the worms. Condiments such as mustard, pepper, onion, garlic, spices, etc., were recommended in the olden days as accessories to anthelmintic treatment. Although *in vil* the anthelmintic power of drugs is enhanced by the presence of these substances, their value in the body is doubtful.

The selection of a preliminary purgative depends on the nature of the anthelmintic to be given. In the case of thymol and carbon tetrachloride, oily purgatives should be avoided because these drugs are soluble in fats and the chances of absorption are increased. Non-absorbable oils such as castor oil or paraffin oil are much less dangerous but even these are not recommended. In the case of drugs like chenopodium, oily purgatives can be advantageously used. Chenopodium oil is readily soluble in castor oil and since it is a local irritant its dilution in non-absorbable oils is advantageous in preventing it from coming in contact with the mucous membrane in concentration which will be injurious. Castor oil also neutralises the paralytic action of chenopodium on the intestinal wall. As a general rule, it is preferable to give saline purgatives because they do not increase the solubility of the drug, they create an osmotic pressure and a flow into the lumen of the gut, instead of away from it and lastly they tend to dissolve mucus and, therefore, expose the parasites to the action of the anthelmintic. Magnesium sulphate or sodium sulphate or a combination of

the two, in dose of one ounce of the saturated solution diluted to two or three ounces is recommended.

2. **The administration of the drug.** The method of administration is determined by the drug prescribed. Water-soluble drugs, if they have not a nauseating taste, may be given in water. Fat soluble drugs, like beta-naphthol and oil of chenopodium, if also water-soluble and absorbable, may be given dissolved in non-absorbable oils. Drugs which are poisonous after absorption in large quantities and which owe their safety to the fact that they are insoluble in water, *e.g.*, thymol, carbon tetrachloride, should under no circumstances be given with fats. It is always safer to avoid the use of oils entirely with male fern. Carbon tetrachloride is insoluble in water and is dangerous if dissolved in oil; it emulsifies when shaken vigorously with milk and the latter forms an excellent medium for its administration. Given in this way it becomes uniformly distributed in the stomach, and the burning sensation which it usually produces is reduced. For nauseating and objectionable-tasting drugs, *e.g.*, chenopodium, filix mas, etc., gelatine capsules are useful. Hard capsules should always be used since soft gelatine capsules do not dissolve in the upper part of the intestine where the action is desired. Soft capsules are best used in the case of worms residing in the lower portions of the gut, *e.g.*, oxyuris, trichuris.

Powdered drugs can be given in the form of powders, cachets or tablets and they are often combined with substances which aid their action, *e.g.*, santonin is combined with calomel. It is better to give some drugs such as oil of chenopodium, beta-naphthol, male fern, etc., in divided dose at intervals of half an hour to one hour as this insures a longer period of contact with the worms. Besides, if toxic symptoms are produced the next dose can be withheld. Division of doses is, however, disadvantageous when a large number of individuals have to be treated at one time. With drugs like carbon tetrachloride this method is contra-indicated as it is liable to promote absorption.

Anthelmintics in the form of enemata are given for parasites residing in the large intestines and many substances have been recommended for this purpose, *e.g.*, sodium chloride, quassia,

turpentine, etc. The enema should be injected as high up into the colon as possible because often the parasites such as oxyuris are situated in the cæcum and in the neighbourhood of ileo-cæcal valve. It should be preceded by a purgative and liquid diet the night before, and a preliminary washing out of the colon with soap and hot water on the morning of the treatment. Sometimes an anthelmintic given by the mouth is effective in this class of infection.

For parasites residing in the tissues, intravenous injections of drugs such as tartar emetic, emetine, etc., are desirable, or anthelmintics may be given by the mouth, *e.g.*, carbon tetrachloride for liver fluke infestations. For lung infestations drugs may be administered by inhalation.

3. **Expulsion of the worms and the toxic drugs.** A post-purgative may have to be used in the case of some of the anthelmintics as they merely stupefy or paralyse the worms or possibly merely irritate them and if they are not quickly swept out in this condition they may revive and obtain a fresh hold. A brisk purgative in these cases quickly washes them out from the intestines while they are still under the influence of the drug. Some purgatives have an irritating effect on the parasites and the increase of peristaltic movements also helps in removing the unattached parasites. Some anthelmintics have a purgative action of their own, *e.g.*, thymol, and with these, post-purgatives are not necessary though they are often administered. One great advantage of a post-purgative is that it hastens the elimination of the anthelmintic after it has acted on the worms, and in this way absorption and consequent toxic effects, if any, are prevented.

The time at which a post-purgative is given is determined by the location of the parasites, *e.g.*, for hookworms and ascaris situated in the upper portion of the gut it may be given simultaneously with the anthelmintic (which is an advantage especially in carrying out mass treatments) or very soon after. For tapeworms, situated lower down, the post-purgative is usually given one hour after; for oxyuris and trichuris an interval of two hours is necessary. It is often advisable to give another purgative on the second day of treatment, as it may eliminate

some of the worms which have succeeded in establishing themselves temporarily in an unfavourable situation lower down in the intestine.

Repetition of courses of treatment especially in case of the intestinal parasites, liver flukes, etc., should never be made in less than one to two weeks, to allow sufficient time for the repair of any damage to the host, caused by the first course. Besides it is seldom possible to be sure that the anthelmintic has failed, in less than a week or even longer. In the case of treatment of tapeworm infection, even when failure is established by unsuccessful search for the head, it is advisable to wait until the parasites have had time to grow again, since the weight of the paralysed or killed worm may draw the head away or may bring it into a position where it is exposed to action of the drug later on.

Criteria of cure. Disappearance of eggs or embryos in the faeces is the usual criterion of cure and is applicable to all intestinal and hepatic flukes and nematode infections except oxyuris. Eggs deposited in the gut prior to treatment may possibly appear in the stool for a few days afterwards. Carbon tetrachloride and some other anthelmintics also have a tendency to inhibit production of eggs for a time, without necessarily killing or expelling worms; in the case of carbon tetrachloride this inhibition may be exerted for as long as twelve days. A re-examination of the stool should be carried out after that period, though a positive examination between the third and twelfth day of treatment conclusively indicates failure. Delayed cures are also effected in the case of hookworm and possibly some of the other parasites; the eggs cease to appear and the worms are expelled a few weeks after the administration of the anthelmintic. This is due probably to the parasites being swept into unfavourable positions in the intestine where they persist for some time but eventually lose their hold and are expelled. It should also be borne in mind that reappearance of eggs two to three weeks after treatment, while it shows that a complete cure has not been effected, does not mean that the anthelmintic has proved entirely useless. In the case of hookworms intestinal anthelmin-

tics often cannot reach the young worms which are hidden in the folds of the mucous membrane or between the villi or which have not reached the alimentary tract. The young parasites and even some of the old ones (*e.g.*, strongyloides) may bury themselves in the mucosa, and may thus be out of reach of the drug.

In the case of oxyuris the search for eggs cannot be relied upon as a criterion of cure, since eggs are not consistently present in the stools but only when female worms become crushed or disintegrated. The entire stools should be searched for the adult living worms. Besides, reinfection not infrequently occurs and oxyuris found in the stools a few weeks after treatment does not necessarily mean that the anthelmintic was ineffective. In the case of tapeworm the criterion of cure depends on the species involved. The common tapeworm of man (*hymenolepis*) can be detected by searching for eggs, but it may be several weeks after treatment that the eggs reappear. This is due to the fact that even though the worms are not expelled the body is broken off just behind the head and it takes time for the segments to re-form. In the majority of tapeworm infections much reliance cannot be placed on searching for eggs; segments may be found in the stool but this takes time. In the case of the tæniæ also the body breaks off and it requires two to three months before the parasite matures and segments reappear.

In the case of schistosome infection, eggs do not always disappear from the urine and fæces immediately after clinical cure since antimony compounds are lethal both to the eggs as well as to the worms and the eggs which are passed subsequent to the destruction of the adult parasites are dead eggs. Their condition can be determined at once by examining them under the microscope or by the hatching test; this is carried out by washing them and putting them into water when the majority of viable eggs hatch out in a few hours and the liberated embryos can be seen swimming about. In the case of *Filaria bancrofti* it is not known how long the embryos circulate in the blood if the parent worms are dead; the criterion of cure has, therefore, to be worked out.

Choice of anthelmintic. Under ordinary circumstances when environmental conditions are not suitable for the transmission of intestinal parasites, helminthic infections are markedly reduced without any treatment whatsoever. The methods of disposal of human fæces are, therefore, more effective in the control of the common human intestinal parasites than the use of the anthelmintics alone. For curative treatment, however, drugs are necessary. The anthelmintic drugs can best be classified into two main groups:—

(1) Those which act on the cestodes or tapeworms; this is called the *cestode group*, e.g., aspidium, kousso, pomegranate bark, etc.

(2) Those which act on the nematodes, called the *nematode group*.

The trematodes come somewhere between the two so far as their reaction to anthelmintic drugs is concerned. They are susceptible to a greater or lesser extent to both groups and more so to those of the nematode group. Santonin, chenopodium, thymol, spigelia, azadirachta, etc., are effective against nematodes and flukes and they have a relatively low efficacy against tapeworms.

Other factors in the choice of an anthelmintic in the selected group must necessarily depend on the indications for, and contra-indications against its use, the particular kind of worm to be attacked, and convenience of administration. For example, carbon tetrachloride cannot be administered to people with cirrhotic livers, oil of chenopodium is contra-indicated for very young children or pregnant women, or beta-naphthol for people infected with malaria. Carbon tetrachloride is particularly effective against necators, less so against ankylostomes and oxyuris, still less against ascaris, and practically useless against strongyloides and trichuris. The oil of chenopodium is relatively more effective against both ankylostomes and ascaris than carbon tetrachloride; santonin is highly effective against ascaris but has no action on hookworms. It sometimes happens that one drug fails in an individual and another succeeds. Sometimes combinations of anthelmintics are of great value, for example, carbon tetrachloride and chenopodium

mixture ; the combination of these two drugs is more efficacious than either drug given alone, and it is possible to reduce the dose of each drug thus rendering them safer.

Effect of temperature. Rivas (1926) pointed out that both protozoan and metazoan intestinal parasites are killed in ten minutes by exposure to a temperature of 45°C. and in a few minutes by 47°C. He suggested intra-intestinal lavage with hot water for parasites living in the small intestine and colonic lavage for those residing in the colon. Hall and Shillinger (1926) experimented on dogs with water at temperatures of 47° to 48°C. administered in quantities of 2 to 4 gallons by means of a duodenal tube. They found that though 97.7 per cent. of ascaris and 77 per cent. of hookworms were removed the temperatures were too high to be safe and many animals died of gastro-enteritis and pulmonary congestion. With lower temperatures such as 40° to 45°C. the mortality was less but the treatment was not so effective. This treatment cannot, therefore, be recommended in human beings.

Experimental investigation of anthelmintic drugs. The experimental work is difficult owing to the impossibility of using artificially infected animals on a massive scale as can be done with protozoal diseases. The effect of anthelmintic drugs can be tested on parasites *in vitro*, but these parasites are difficult to obtain and to keep alive. Sollmann (1918) employed earthworms for testing the action of anthelmintic drugs *in vitro* and found that the drugs which are non-toxic to these worms are not likely to be active, while drugs which are lethal to them have possibilities of effective anthelmintic action. In some cases the toxicity to the earthworm runs parallel with their toxicity to parasitic worms, and a method of assaying these drugs with earthworms has been evolved. The worms are distributed into separate vessels containing carefully measured volumes of liquid; a different amount of the drug to be tested is put in each, except in one vessel which is kept as a control. The behaviour of the worm is then noted. Extreme restlessness or spastic contractions indicate irritation—possibly vermifugal activity. The time of death is noted and the results are compared with a similar series made with a standard preparation. Aspidium, chenopodium, santonin, spigelia, etc., can all be standardised by this method.

In vitro tests are, however, merely a preliminary step and must be followed by *in vivo* tests. In most cases dogs respond to anthelmintic drugs in much the same way as human beings though perhaps they are more resistant; they are, therefore, particularly suited for anthelmintic experimentation. As a rule with most of drugs known, a dog weighing 20 kilogrammes can be given the same dose as an average adult human being, but this may not be so in case of all drugs. The worms expelled by the drug are carefully counted and the results are

compared with the number of worms still present on post-mortem examination. Darling and Smillie's standard test treatment method is applicable to man. The drug is first given to a series of infected individuals and the worms which are expelled are carefully searched for and counted. Subsequently a full dose of an anthelmintic of known efficacy is administered, and the worms eliminated are compared with those expelled by the experimental drug. All these worm count methods are very laborious and they are not thoroughly reliable. The worms are mostly expelled in the first 18 hours after administration of the drug but elimination may continue for five days and, therefore, all stools during this period should be saved and examined; some worms may even be digested.

Another method of determining the efficacy of anthelmintic medication is by making differential egg-counts before and after the treatment. In the case of necators for example, the number of eggs produced by a female per day is fairly well known and the number of worms harboured can be roughly estimated by determining the average number of eggs per gram of faeces for a period of not less than three days. Such determinations made before the treatment and then a week or ten days after the treatment enable us to know the relative number of female worms eliminated. In most infections the number of males and females is roughly about equal.

Correlation between chemical composition and anthelmintic action of drugs. The study of the chemical constitution of the active principles isolated from drugs has led to the synthetic production of important compounds with marked physiological properties. Pharmacologists and chemists have been working together to find out what portion of the molecule is responsible for the physiological effects produced by a drug, and this has laid the foundation of the subject of correlation of chemical composition to physiological action of drugs. It is found that though in some cases a distinct relationship can be traced between these two, in the majority of cases the relationship is very obscure and difficult to understand. Very small changes in the chemical constitution completely change the physiological action of drugs, e.g., cocaine has strong local anaesthetic action while alpharocaine has none; l-adrenalin is much more active than d-adrenalin. Changes in the chemical composition of compounds produce changes in their volatility, solubility, osmotic properties and diffusibility, and physiological properties are also altered.

The study of the relationship between the chemical constitution and the anthelmintic action of compounds was first taken up by Hall and Meyer Widgor (1917-18) but their work was interrupted by the War. Caius and Mhaskar made an elaborate study of a large number of anthelmintic drugs and attempted to correlate the efficiency of certain drugs with certain of their chemical constituents. Some very

remarkable facts have been brought to light in connection with the anthelmintic action and toxic effects of these drugs:--

(1) Hydrogenation of benzene lowers the toxicity towards the parasites but raises the toxicity towards the host as is the case with menthol.

(2) Total destruction of the benzenoid structure leads to the formation of non-anthelmintic toxic compounds.

(3) Esterification of the phenolic-hydroxyl group leads to the formation of non-anthelmintic non-toxic compounds, *e.g.*, thymotal.

(4) The mere presence of the phenolic-hydroxyl group does not always confer anthelmintic properties, *e.g.*, iso-amyl-phenol or iso-butyl-phenol which contain it are both inactive.

(5) The active anthelmintic principles in oil of chenopodium (paracymene, phellandrene, ascaridol) and thymol, contain free phenolic hydroxyl to which are attributed their anthelmintic properties.

(6) Methyl alkyl appears to intensify the anthelmintic action of phenolic-hydroxyl, *e.g.*, methyl-salicylate has marked anthelmintic properties while other salicylic acid compounds such as aspirin and salol are inert.

(7) Neither alcohol nor aldehyde groups have any anthelmintic properties.

(8) The anthelmintic activity of carbon compounds appears to be correlated with the chlorine content.

It will be seen, therefore, that in the majority of cases the relation between chemical constitution and their physiological action is not very clear. Change in chemical composition completely changes the physical properties of compounds. Their volatility, solubility, osmotic properties, ionisation, etc., undergo a complete change and so their absorption into the system and the physiological effects produced are also modified. In the present state of our knowledge of the changes going on inside the body of a living cell, it is impossible to speculate further.

INTESTINAL HELMINTHIASIS

In a general way parasitic worms fall into two groups as regards their reaction to anthelmintics; the nematodes and flukes respond to treatment with one group of drugs, which are classed here as the nematode group, whereas the tapeworms respond very feebly to these drugs, but are actively attacked by an entirely distinct group, which we therefore refer to as the cestode group. There are, however, some drugs which fall under both the groups.

1. Nematodes

Oxyuris vermicularis or threadworms. These parasites not only infest the colon and rectum but the upper portions of the gut as well. The treatment, therefore, consists of :—(1) The removal of the parasites and the eggs from the rectum and perineum. This is done by giving high and low enemas first daily and later bi-weekly or weekly. The patient should be put in knee-elbow position and large enemata of 1 to 2 quarts, of tepid or warm fluid are slowly given. The solutions used are 1, 2 or 3 per cent. sodium bicarbonate, sodium carbonate, sodium borate, or sodium chloride and as much as 1 to 2 pints (0.5 to 1 litre) or more may be given. Three to 4 ounces (90 to 120 c.cm.) of lime water are sometimes added to each injection, or 5 per cent. solution of boric acid may be given by itself. Soap water is a useful vehicle for oil of turpentine or oil of eucalyptus which are added in doses of 1 to 2 drachms (4 to 8 c.cm.) or more. The following are also used :—A decoction made from eucalyptus leaves ; 20 drops of benzene added to 1 pint of warm water or soapsuds ; a decoction made by boiling one ounce (30 gm.) of chips of quassia in 1½ pints (750 c.cm.) of water boiled down to a pint (500 c.cm.) and strained ; 0.4 to 0.5 per cent. of quinine solution ; 15 to 30 grains (1 to 2 gm.) of salicylic acid to a pint of water ; ferric chloride 4 drachms (15 c.cm.) to a pint of water ; ferrous sulphate 4 to 10 grains (0.2 to 0.6 gm.) in a pint ; papain 10 to 20 grains (0.6 to 1.2 gm.) in a pint ; hydrogen peroxide 1 in 5 to 1 in 10 ; vinegar diluted with 2 to 3 volumes of water ; naphthalene 15 to 30 grains (1 to 2 gm.) in 100 c.cm. of water or 3 ounces of olive oil ; tannin in the form of an infusion or decoction of krameria, logwood, catechu, kino and tincture of aloes (drachm to the pint).

In place of or following the enema, suppositories of ammoniated mercury, naphthalene, quinine sulphate or santonin may be employed. The perineum and anal folds (in females, the vulva and vagina) may be swabbed with 1 to 2 per cent. phenol and dusted with boric acid or 5 to 10 per cent. boric ointment employed to prevent reinfection.

To expel the parasites from the jejunum where they occur in large numbers, give calomel and sodium phosphate, or sodium sulphate or magnesium sulphate; santonin or thymol may also be given.

Trichuris trichiura or trichocephalus dispar or whipworms. The measures used against threadworms are less effective against whipworms. The best drugs are:—Santonin and calomel gr. 2 to 3 each; oil of chenopodium 5 to 15 minims (0.3 to 1 c.cm) in the form of an emulsion; oleo-resin of aspidium; thymol 15 grains (1.0 gm.). The number of doses to be given depends on the effects produced on the patient. The drug should always be followed by a purgative. The stools must be repeatedly examined and treatment repeated until no parasites are found.

Ascaris lumbricoides or roundworm. Infection with these parasites is very prevalent in many insanitary tropical countries and it is often associated with ankylostomes. They may give rise to intestinal obstruction, perforation of the intestines, intraperitoneal abscess, ileus and meningitic symptoms. The drugs commonly employed are santonin, oil of chenopodium and spigelia. Santonin and oil of chenopodium are usually effective. The day before the treatment a saline purgative such as sodium phosphate or sulphate or magnesium sulphate may be given. At bed time the bowel is washed with a soap-sud enema. The following morning the anthelmintic is given in divided doses. Santonin usually combined with calomel is given at night followed by a saline the following morning. It is advisable to repeat the treatment after a week or two to make sure that all the worms have been expelled.

Ankylostoma duodenale and necator americanus (hookworms) and strongyloides. Infestation with necators is common in Southern India; in northern parts of India ankylostoma is common; infections are generally of mixed types. Milder infestations such as those containing 100 to 500 eggs per gramme of faeces are harmless. Experienced workers say that about 100 worms are required to produce any pathogenic effects and 500 to 1,000 worms must be present for at least six months to produce well marked symptoms; 3,000 to 4,000 may be present

when severe degrees of anæmia exist. The other school holds that a small number of worms such as 10 or 20 may affect general health and working power, they therefore advise wholesale treatment. Infections are present both in tropical and subtropical zones all over the world. In India the heaviest infestations are found in places which experience heavy rainfall, e.g., Assam, Burma and Malabar, and moderate ones in Bengal, Behar, the United Provinces and the Southern Bombay coast. Eighty to 100 per cent. of infections occur in the country and 91 per cent. in the urban areas with an average only of 10 worms. Carbon tetrachloride, tetra-chlorethylene, thymol and chenopodium are given (see description of these drugs). After an interval of a month the stool should be examined and if ova are found the treatment is repeated.

Strongyloides often occurs in association with hookworms or independently; this infection is commoner in the Punjab and Rajputana. The females burrow into the intestinal wall and are difficult to dislodge.

II. Cestodes

A number of species of cestodes infest man, but only four are important: *Tænia saginata* or the beef tapeworm occurs all over the world. The heaviest incidence has been recorded in North China. *T. solium*, the armed or pork tapeworm enters the body through eating pork, the cysticercus stage (*C. cellulosæ*) being found in various parts of the body including the heart and brain. *Diphyllobothrium latum* or *Tænia lata*, is the broad or fish infesting tapeworm which causes profound debility and anæmia. It is a common infection in Canada and Northern Europe. *Hymenolepis nana* or *T. nana* is a small tapeworm occurring in man and rats in warm countries in many parts of the world. It is widespread in India. *H. diminuta* is another allied species. Prevention of infection in all cases should be attempted by thorough cooking of all contaminated meat; the food should be prevented from contamination by faeces of rats, mice, cats or dogs. Proper disposal of faeces is necessary to prevent spread of infestation.

The preliminary preparation of the patient in case of tapeworm infection must be thorough. The routine of treatment is described under aspidium. The patient should keep in bed after taking the drug. The stools should be passed in a chamber pot half full of water so that the worm can be recognised; this should be examined carefully to see if the head has been passed. In case the head is passed no more anthelmintic should be given but the stools should be watched to make sure that there is not a multiple infestation. If only segments have been passed the treatment should be repeated in full after 10 to 14 days. If there is doubt about the expulsion of the head, it is best to wait for 8 to 10 weeks, watching the stool in the meanwhile for reappearance of segments. If no ova or segments can be detected the head has been expelled. If *T. solium* is found, prompt treatment should be given since there is danger of cysticercus infection.

The cestode group of anthelmintics includes the phloroglucinol series, *i.e.*, male fern which is entirely successful in dwarf tapeworms, and also koussou and kaimala; pomegranate bark or its active principle pelletierine which should be employed when male fern fails; the active principles of areca nut (arecoline); peps or pumpkin seeds are remedies against *T. saginata*. Other less important agents are cocoanut, butyl-chloral hydrate, oil of turpentine, brayera, etc.

CHAPTER II

ANTHELMINTICS ACTING ON CESTODES

MALE FERN AND ALLIED DRUGS

Male fern, Koussou and Kamala are the three important drugs included in this group. All these drugs, though derived from different sources are intimately related to each other from a chemical as well as from a pharmacological point of view. The active principles in all are chemically allied bodies, *i.e.*, derivatives of phloroglucin.

ASPIDIUM (MALE FERN)

Synonyms:—*Stipides aspidii*, *Radix Filicis Maris*, Sweet brake.

This is one of the oldest anthelmintic drugs known and was used by the ancient physicians, Pliny and Galen. *Aspidium filix mas* and *Aspidium marginalis* are the two well-known varieties of ferns which are recognised in the British and United States Pharmacopœias. They both contain the same active principles, but the former yields smaller quantities of the rhizome. Several other ferns such as *A. spinulosum* and *A. dilatatum* growing in Europe and *A. anthelminticum* growing in South America contain similar active principles and properties. The rhizome and stipes of *Dryopteris filix mas* (Linn.) Schott (Fam. Polypodiaceæ) are chiefly used.

Chemical composition. The chemical nature of different constituents of the rhizome is not quite clear. This is due to the fact that most of the compounds are unstable bodies and undergo chemical changes even in the dry rhizome. The active principles are a number of non-nitrogenous substances the more important of which are as follows:—*filmaron* 5 per cent., *fillicic acid* 2 to 4 per cent., and smaller quantities of aspidin, aspidinol and fillicic acid. In addition there are tannic acid 10 per cent.; inactive fillicic anhydride (filicin) produced in old specimens by transformation of fillicic acid, 19 to 31 per cent.; a green fixed oil 6 to 7 per cent.; a volatile oil 0.02 to 0.04 per cent.; an uncrystallisable sugar, 11 per cent.; resin, starch, and wax.

The active substances are compounds of butyric and isobutyric acids with phloroglucin and its homologues. They are insoluble in water and soluble in fats and oils. The essential oil is light yellow in colour and gives it its peculiar odour. The poor absorption from the gut is dependent on the insolubility of the active principles in water.

Fillic acid or *filicin* occurs in two forms, (1) a crystalline inactive form and (2) an amorphous form which is said to be mainly responsible for the therapeutic activity of the drug. The crystalline form is the lactone of the active amorphous form and the latter readily changes into the former. This is the reason why the rhizome and its preparations deteriorate so quickly.

Pharmacological action. Straub has shown that the active principles of male fern are powerful poisons to smooth muscle and they also attack striated muscle. This quality of the drug probably accounts for its vermifugal action on the tapeworm. *In vitro* experiments show that non-striated muscle of invertebrates such as molluscs, annelids, echinoderms, crustaceans, etc., is very sensitive to filicic acid bodies and is rapidly paralysed by its direct action on the muscle fibres.

Internally, filicic acid has a strongly irritant action on the gastrointestinal tract and may produce vomiting and blood-stained diarrhoea, and in excessive doses collapse and death. The irritation of the gastrointestinal tract sets up reflex uterine contractions. It should not, therefore, be given to pregnant women. The liver is affected even after moderate dose producing bilirubinæmia, large doses may produce jaundice and cirrhosis of the liver. The heart muscle is depressed and the beats are slowed and weakened. The spinal cord is stimulated, at first producing twitchings and with large doses convulsions occur; later, ascending paralysis of the spinal cord sets in, and death occurs from failure of the respiratory centre. Small amounts of the active principles are absorbed from the gut and filicic acid and its decomposition products are excreted by the kidneys.

Principles of administration of Filix Mas. The fresh ethereal extract is usually administered in dosage of 10 to 30 minims every half an hour in capsules till the full dose is given; a grain of calomel may be added to each capsule. It may also be given in an ounce of milk with the yolk of an egg or some flavouring agent such as cinnamon oil or chloroform water, to conceal its nauseating taste. Two to 10 minims (0.1 to 0.6 c.cm.) of chloroform are said to enhance its efficacy. The oleoresin is given in a 30-grain dose (2 gm.) to an adult and $7\frac{1}{2}$ to 15 grains (0.5 to 1.0 gm.) for a child. It is best given in divided doses 10 to 30 minutes apart, the last dose being followed in $\frac{1}{2}$ to 1 hour by a full dose of magnesium

sulphate. Pills coated with keratin are preferred by some. Clayton Lane and Low recommend the following method of administration of the drug: liquid diet for two days; calomel or a saline purge in the afternoon of the second day; a cup of black coffee the next morning (third day); then one capsule containing 30 minims of the liquid extract at intervals of $\frac{1}{2}$ hour till three such are given. A drachm of brandy with 15 minims (1.0 c.c.) of chloroform may be given with the first dose, to prevent vomiting. A saline aperient (Epsom salts, Carlsbad salts or sodium sulphate) is given two hours after the last dose, to wash out the parasites and the drug.

In treating cases with the extract of male fern, three things are essential: (1) The alimentary canal should be properly prepared for the reception of the drug. The head of the parasite is imbedded in the intestinal mucosa between the villi, and unless the bowel is empty the drug does not reach it. (2) The extract, if used, should be fresh. This is important as the power of the extract to retain its potency is uncertain. The active principles of filix mas are easily destroyed and it has been noticed by several observers that the dried rhizome of the male fern gradually loses its activity on keeping. The extract should be made from specimens that have not been kept for more than a year. (3) The post-purgative given should be a powerful one, so that the head of the worm loses its hold and is expelled from the intestine.

All stools passed for 24 hours after treatment should be saved and passed through a fine sieve to search for the presence of the scolex or the head. If the head is not found, cure has not been effected and another course of treatment will be necessary. In such cases, treatment might be repeated after an interval of 10 to 15 days following the first course, as the drug undoubtedly has a cumulative toxic effect. The possibility of there being more than one worm should be borne in mind and this can be usually determined by piecing together the expelled segments.

Anthelmintic effects. The older physicians used this drug against all forms of helminthic infections, but recent work has

shown that it has little value against ascaris, hookworms and other nematodes. Against whipworms (*trichuris*) a small dose of the extract ($1\frac{1}{2}$ drachm) daily 2 to 3 days in succession and repeated after an interval of 10 days is effective. It is useless in schistosomiasis, somatic *tæniasis*, etc., although the drug is said to have some effect against liver flukes. On the cestodes the drug has almost a specific effect though failures are not uncommon. The failures recorded are mostly due to the poor quality of the drug obtained from the market and the careless preparation of the patient. Rarely, the parasites themselves show extraordinary resistance to the drug and cannot be expelled even after 5 or 6 treatments.

In Europe and America, *felix mas* is commonly used against *tænia* or *diphyllbothrium*. If the patients are properly prepared according to Lane and Low's method, 50 per cent. of cases of *Tænia saginata* infections are cured with a single treatment. It acts on *Hymenolepis nana* as well as the large *tæniæ*s, but as the former are small and are embedded in the mucus it is difficult for the drug to reach them. The rarer tapeworms of man, e.g., *Dipylidium caninum*, *Hymenolepis diminuta* and *Bertiella satyri* which are not normal human parasites, are more easily expelled than the species which have adapted themselves to the human host.

Signs and symptoms of poisoning. Male fern was formerly considered to be a harmless drug in man but recent experience has shown that it is very toxic and deaths have been reported from its use. Toxic doses vary within wide limits depending on the active principles present and also on the resistance of the patient. Anæmia, debility, old age and infancy are predisposing factors to poisoning. The presence of fatty substances in the gut increases absorption. Toxic symptoms are likely to occur after 2 to $2\frac{1}{2}$ drachms (8 to 10 gm.) of the extract, but severe poisoning has occurred after 1 drachm (4 gm.) given in a day. More than 2 drachms should never be given in 24 hours.

The chief symptoms in these cases are headache, vertigo and bilirubinæmia; slight jaundice frequently occurs. In moderately severe doses the symptoms are those of gastro-en-

teritis, *e.g.*, vomiting, abdominal pain, blood-stained diarrhoea ; headache, dizziness, shortness of breath, dimness of vision or yellow vision and sometimes amblyopia may be present. The patient becomes dyspnoic, looks drowsy and feeble. The kidneys are irritated and albumin is often present in the urine. Hæmoglobinuria and hæmaturia rarely occur. In very severe cases the patient becomes delirious, gets severe cramps and violent convulsions ; he loses consciousness, respiration becomes slow and shallow, the pulse weak and imperceptible and there is marked cyanosis. Convulsions are followed by muscular relaxation, immobility of pupil, and abolition of reflexes are common. Optic neuritis resulting in temporary or even permanent blindness has been observed. Death occurs from respiratory failure or paralysis of the heart.

Treatment of poisoning. In treating cases of male fern poisoning, the stomach and the intestines should be evacuated at once. A quickly acting purgative such as magnesium sulphate or citrate may be given at once. Such purgatives as castor oil or croton oil should be avoided. Demulcent drinks should be given if diarrhoea and vomiting are present. The patient should be kept strictly in a recumbent posture, for there is danger of cardiac failure, and he should be kept warm. Cardiac stimulants, such as aromatic spirit of ammonia, spirit of ether or camphorated oil should be administered. If collapse occurs, give injections of pituitrin, adrenalin or ephedrine. Convulsions if present should be controlled by inhalation of chloroform or ether ; bromides may be given. If paralysis is present, give atropine or strychnine. Alkalies may be administered if hæmaturia is present.

Precautions and contra-indications. Preliminary preparatory measures should not be carried to extremes and starvation is not indicated ; the patient should be given a light diet and a preliminary purge. The administration of the extract should be followed up by a strong active purgative, so that it is eliminated from the gut without delay. Under no circumstances oily cathartics like castor oil, which facilitate absorption of the drug, should be given, for in 57 per cent. of cases severe poisoning has occurred subsequent to its administration. Other

solvents such as fats and alcohol should be avoided. A rapidly acting purgative such as magnesium sulphate, should be administered. Compound jalap powder, senna or calomel may be given previously or along with the drug. Weak and emaciated patients are not suitable cases for the administration of the drug. The drug is contra-indicated when ulceration of the stomach and duodenum is present because of its irritant action and the liability of greater absorption from the ulcerated surface. It should also not be given in pregnancy, affections of the heart, liver and kidneys.

Preparations.

Extractum filicis liquidum (B. P.) is prepared by ether extraction and contains not less than 20 per cent. of filicin. Dose 45 to 90 minims (3 to 6 c.cm.); as much as 2 drachms may be given. The extract loses its activity on keeping. The specimen of a good active extract is dark green in colour, while an extract which has turned brownish yellow and has a crystalline deposit at the bottom has deteriorated. As the extract has a very disagreeable taste and smell it is often given in capsules containing 15 minims each. Yeo gives capsules with one grain of calomel each. **Haustus filicis liq.** is in use in many hospitals. It consists of liquid extract of filix mas one drachm, syrup of ginger one drachm, tincture of quillaia $\frac{1}{2}$ drachm and peppermint water up to one ounce.

Oleoresina aspidium (U.S.P.) made by percolation with ether, is a solid substance and does not deteriorate so rapidly as the liquid extract. Dose 30 grains (2.0 gm.) once a day.

Filmaron is soluble in ether, alkali, and sparingly in alcohol. Dose 10 to 15 grains (0.6 to 1.0 gm.).

Amorphous fillic acid. Dose 8 to 15 grains (0.5 to 1.0 gm.) in a capsule.

KOUSSO OR CUSSO

Koussou is the dried female flowers of *Hagenia abyssinica* also known as *Brayera anthelmintica*, family Rosaceæ. The plant grows in north-eastern part of Africa and is cultivated in Abyssinia. It has been used as an anthelmintic from very ancient times. The entire panicles of the pistillate flowers collected after pollination, and dried in the Sun are most suitable for vermifugal purposes. Only the panicles are official in the pharmacopœia. Koussou has no odour but has a bitter acrid

taste. The drug loses its activity by ageing and, therefore, should be used as fresh as possible.

Chemical composition. Koussou is composed of two distinct parts: (1) the glands of the flower panicles containing the active principles and (2) sharp microscopic hairs which are mechanically irritating to worms and to the gut. The active constituent of koussou is *kosotoxin* which is a pale yellow, amorphous powder, insoluble in water but soluble in alcohol and ether; it melts at 80°C. By caustic alkalies it is converted into *kosin* or *koussein* (brayerin) which occurs in yellow rhombic crystals insoluble in water but soluble in alcohol, ether, and benzene and has a bitter acrid taste. Besides these it contains a volatile oil, resin, tannic acid, oil and gum. The commercial *koussein* is a mixture of various principles. By the action of zinc dust and sodium hydroxide *kosin* is split up into isobutyric acid and phloroglucinol which brings it closer chemically to anthelmintic ferns.

Pharmacological action. Kosotoxin is a protoplasmic poison. In frogs it acts like curare and paralyses the motor nerve endings of the striped muscle and finally the heart. In mammals, it stimulates the medullary centres. Both tapeworms and ascaris die when exposed for 30 minutes to an infusion of koussou.

Therapeutic uses. Koussou is used as a tæniacide and is said to be the safest among this class of drugs. Its efficacy depends on its freshness. It is equally effective against all species of tapeworms and has also been used against ascaris. Koussein in small doses is preferable to other preparations. Usually 15 to 60 grains (1 to 4 gm.) are given in a capsule in divided doses hourly or half hourly, in much the same way as the oleoresin of male fern. The last dose is followed by a purgative. The usual dose for an adult is 2 to 4 drachms (4 to 8 gm.) of the powdered flowers. No fasting on the previous day is necessary. The drug is given in the morning on an empty stomach after the bowels have been moved, and no food except clear soup or weak tea are given till the worms are expelled. The infusion may be given in doses of 8 ounces (250 c.cm.) at once, or divided into 2 or 3 portions. As a rule, no after purgative is necessary, but if the bowels do not move a saline purgative should be given. Koussou is both a tæniacide and a tæniacide, the latter property is dependent partly on the purgative action of the active principle and partly on the numerous fine pointed hairs which irritate the worm and drive it out.

Toxic effects. Kosotoxin is a toxic drug, 1 mgm. being fatal in a frog and 50 mgm. per kilo. in rabbits, dogs and cats. The lethal dose in man is not known. Moderately large doses produce nausea, vomiting and faintness; purgation usually begins after an hour. Larger doses produce gastro-intestinal irritation with continued vomiting and violent purgation. If the drug is absorbed there is headache, vertigo, mental disturbance, precordial pain, dyspnoea, painful micturition and sometimes convulsions.

Kousso and its preparations are contra-indicated in pregnancy, debility, and organic diseases of the heart and kidneys.

Preparations.

Powdered dried panicles of the pistillate flower is given in doses of 2 to 4 drachms (8 to 16 gm.).

Kosin (N. O.) is a yellowish bitter crystalline mass. Dose 7 to 15 grains (0.45 to 1.0 gm.) repeated every half hour till 4 doses have been given; last dose followed by a purgative.

Infusion brayeræ or infusion of kousso is prepared by pouring 1,000 c.cm. of boiling water over 50 gm. of powdered braver and allowing it to stand till cool. It is given without straining. Dose 6 to 10 ounces (190 to 300 c.cm.).

KAMALA

Synonyms:—Rottlerin, Kameela, Reroo

Kamala is a purplish-red or brick-red powder derived from the glands and hair of the fruit of *Mallotus philippinensis*, an evergreen tree belonging to the Euphorbiaceæ or spurge family. It has long been used as a tæniacide in India and at one time had gained a considerable reputation as an anthelmintic and was included in the British and United States Pharmacopœias. Further experience, however, showed that its action was uncertain and it was, therefore, discarded.

Active principles consist of:—(1) a brownish-red resin or resinoid *rottlerin* (mallotoxin) which can be easily converted into methyl phloroglucin. It is probably the same as *kamaline*. (2) *Iso-rottlerin* is probably impure *rottlerin*. Besides these, there are resins, starch, traces of a volatile oil, oxalic and citric acids. Powdered kamala is given in doses of 2 to 3 drachms mixed with milk, curds or honey. The drug met with on the market is often adulterated with ferruginous sand, red brick dust, ferric oxide, dyed starch. etc.

Action and uses. The drug irritates the gastro-intestinal tract and even in therapeutic doses produces considerable nausea and increase of peristaltic movements of the gut. It has thus a purgative action. Large doses produce gastro-intestinal irritation and set up vomiting and violent purging.

The chief advantage of this drug appears to be that it can be safely given without any preliminary preparation of the patient; no post-purgative is necessary. It is much less efficient against tapeworm than male fern. It is useless against hookworm, ascaris and whipworm. It is a mild drug and is only indicated in children and debilitated individuals in whom extract of filix mas is not advisable.

Kamala is also applied externally in 10 per cent. lotion and ointment for scabies and other parasitic affections of the skin.

OTHER ANTHELMINTICS

Pomegranate or granatum. The bark of the pomegranate tree, *Punica granatum* Linn. (N. O. Lythraceæ), has been employed as an anthelmintic in India from time immemorial and was used by the Romans. Both the root bark and the stem bark have been used but root bark is preferable inasmuch as the alkaloidal content is greater than that of the stem bark.

Chemical composition. The active principles of the bark are 4 alkaloids: (1) *Pelletierine* or *punicine*, the most important of the group, is a colourless volatile liquid which turns dark on exposure. It has a boiling point of 195°C. (2) *Iso-pelletierine*. Only these two alkaloids are supposed to possess activity against tapeworms. (3) *Methyl-pelletierine* closely resembles pelletierine and (4) *Pseudo-pelletierine* also known as *methyl granatine*. The last two alkaloids are inactive. The mixed alkaloids were put on the market under the name of pelletierine (the names punicine, isopunicine, etc., have been adopted for the pure alkaloids). The bark also contains *puni-cotannic acid* which has a tæniastatic action, and it renders the alkaloids insoluble and prevents their absorption from the gut. The sulphates of the alkaloids are soluble and are readily absorbed. This explains why the bark is a better anthelmintic.

Pharmacological action. The alkaloids pelletierine and iso-pelletierine have a local irritant action and even in small doses they produce vomiting and colicky diarrhoea. They are absorbed from the gut if given in soluble form and are readily destroyed in the body. They act on the nervous system producing headache, vertigo, drowsiness, ocular disturbances and dimness of vision. Toxic doses have a paralyzing effect on the motor nerve endings and give rise to numbness and cramps of the lower extremities, paralysis of the diaphragm and convulsions from asphyxia. In rabbits there is progressive mus-

cular paralysis. Unstriped muscle fibres are first stimulated then paralysed. *Tænia saginata* which usually live for hours in a solution of sodium chloride kept at body temperature, are killed in about 10 minutes if 0.01 per cent. pelletierine is added to the solution.

Anthelmintic use. The fresh bark is said to be a fairly good anthelmintic against tapeworms. The bark is, however, unpleasant to take and on account of the large quantities of tannic acid present it is liable to produce nausea and vomiting. Experience shows that it is also uncertain in its action. Pelletierine in the form of tannate given in doses of 2 to 8 grains (0.12 to 0.5 gm.) acts as an excellent tæniacide without producing marked toxic effects. The soluble salts are absorbed and produce toxic effects. Absorption is favoured by alcohol, and for this reason fluid extract is not such a good tæniafuge as the decoction or powdered bark. If the preliminary preparation of the patient by dieting and purging is carefully attended to in the same way as with aspidium, pelletierine tannate will seldom fail to produce an efficient vermifugal action. After liquid diet for two days and a strong preliminary saline purgative the night before treatment, pelletierine is given in the morning in sweetened water followed by a brisk saline cathartic half an hour later. The patient should stay in bed after taking the medicine as dizziness is always experienced. The worms are expelled 2 to 4 hours later. This drug ranks next only to *filix mas* as a tæniacide, and is specially recommended against infestations with *Tænia solium*. Against *Hymenolepis nana* it is not effective.

Toxic effects. Large doses of the decoction or the alkaloids produce headache, dizziness, dim vision, nausea, vomiting, diarrhoea, weakness of the limbs followed by paralysis. Drowsiness and coma may supervene. Serious disturbances in the eyeball such as dilatation of the pupil, retinal congestion and amaurosis may occasionally occur.

Treatment of poisoning. Treatment is largely symptomatic; rapid emptying of the bowels, administration of stimulants and artificial respiration when the respiratory muscles are affected, are important. A brisk purgative such as calomel and saline should be given immediately. If the patient is seen soon after ingestion of a large amount of the drug, gastric lavage is indicated. Demulcent drinks to soothe the gastro-intestinal irritation are recommended. Tannic acid may be given. Stimulants such as strychnine are indicated.

Preparations.

The dried powdered bark is given in doses of 20 to 40 grains (1.3 to 2.0 gm.).

Granati (U.S.P.X.) is prepared by exhausting the powdered bark with 37 per cent. alcohol and 10 per cent. glycerine. Each c.cm. represents 1.0 gm. of the drug.

Pelletierine (mixture of the alkaloids), dose 2 to 6 grains. **Ext. Granati Liq.**, dose 30 to 120 minims. **Pelletierine sulphate**, dose 2 to 3

grains. **Pelletierine tannate** (B. P.) is a yellow, amorphous powder, dose 2 to 8 grains. **Pelletierine hydrobromide** is a brownish viscid liquid, dose 2 to 8 minims.

Areca nut. Synonyms:—*Arecae semina*, betel nut. Areca nut is the seed of *Areca catechu* belonging to the family *Palmaceae*. It has been used for a long time in India and China as an anthelmintic both for man and animals and was considered so effective that it was included in the British Pharmacopoeia. Recent work has thrown considerable doubt on its anthelmintic value.

Chemical composition. Several alkaloids have been isolated from the seeds which are all chemically related to each other. These are, *arecoline* and *arecaine* which occur in the same proportions (0.1 per cent.), *arecaldine* and *guvacine* occur only in traces. *Arecoline*, a colourless oily liquid is physiologically active; the other three are probably inactive. To it the anthelmintic and sialogogue properties are mainly to be attributed. There is also an essential oil (which contains laurin and myristin), several sugars, iron, magnesium and other salts.

Pharmacological action of arecoline. Arecoline base is not soluble in water and is not readily absorbed; the soluble salts of arecoline are rapidly taken up from all mucous membranes and poisoning can be produced by instilling a 1.0 per cent. solution into the eye. It is excreted unchanged in the urine. The action of arecoline resembles that of pilocarpine and physostigmine and is chiefly on the autonomic and central nervous systems. It stimulates the nerve endings of the plain muscles and glands; there is inhibition of the heart and fall of blood pressure, constriction of the pupil, contraction of the bronchial musculature and definite increase of the peristaltic movements of the intestine owing to stimulation of Auerbach's plexus; the flow of saliva and sweat is stimulated. In the heart the entire intra-cardiac inhibitory nerves are stimulated and the heart, whether intact or isolated, stops in diastole. The blood vessels are not affected and the blood pressure falls owing to the action of the drug on the heart. The spinal cord is at first stimulated and then paralysed; the respiratory centre is depressed and the vagus centre is stimulated. In frogs convulsions resembling those by strychnine are produced; the heart becomes slowed and finally stops in diastole. In cats and dogs there is profuse salivation, vomiting, diarrhoea, increase of spinal reflexes and tetanic convulsions. Tapeworms and liver flukes placed in dilute solutions of arecoline salts are rapidly paralysed.

Anthelmintic uses. Areca nut is not an effective drug against nematodes and its efficacy against tapeworms and flukes is doubtful. The powdered nut in doses of 1 to 3 drachms (4 to 12 gm.) is given in syrup. It has undoubtedly an irritant action on the gut and produces purgation, but it does not expel worms. Arecoline salts are given by the mouth in man in doses of 1/15 to 1/10 grain (4 to 6 mgm.) or

subcutaneously $\frac{1}{2}$ of the amount. One to 2 grains are given to cattle to relieve colic.

Toxic effects. Arecoline in pure condition is a toxic drug. As it is readily absorbed from the gastro-intestinal tract it is considered dangerous for use as a tæniacide. Arecoline poisoning, however, might occur when large doses of the powdered nuts are administered. The symptoms resemble those of fungus poisoning (muscarine) and consist of vomiting, diarrhoea, colicky pains, marked salivation, laboured breathing, tremors, convulsions, coma and death. If toxic symptoms supervene, rapid evacuation of the bowels and administration of cardiac and respiratory stimulants are indicated.

Preparations.

Dry and fresh powdered seeds, dose 1 to 3 drachms (4 to 12 gm.).

Arecoline dihydrobromide and dihydrochloride occur in white crystals soluble in alcohol and in water. It is official in some of the pharmacopias, dose 1/120 to 1/40 grain.

Pepo. Pumpkin seeds. The seeds of *Cucurbita pepo* and *C. maxima* (melon pumpkin) have been used for ages as a household remedy against tapeworms. They are said to have succeeded when other drugs have failed. It is difficult to say how the anthelmintic action is produced. There are no active principles, as far as is known, and the therapeutic activity, if any, is probably due to mechanical action of the sharp edges of the bruised seeds.

Chemical composition. *C. pepo* contains 40 per cent. of a fixed oil and 30 per cent. of starch, a soft bitter acrid resin which is said to be the active constituent, a volatile oil, and 30 per cent. of starch, sugars and proteins. *C. maxima* contains 30 per cent. of a fixed oil and an acid resin, which was supposed to be responsible for the anthelmintic activity of the seeds but later proved to be useless.

Pharmacological action. *Ascaris*, *Tænia saginata* and *Diphyllobothrium latum* are said to be irritated and dislodged by the husks and paralysed by the oil and resin. *Tænia solium* and *Hymenolepis nana* are apparently more resistant. *In vitro* studies by Power and Sollmann have shown no destructive action. Neither the seeds nor the oil have any marked physiological activity.

Anthelmintic effects. The seeds administered should be fresh, certainly not more than a month old. Two to four ounces are administered crushed or beaten into a paste with water and finely divided sugar, the whole being made up to one pint. Sometimes a little milk is added. The usual preparatory dietetic measures are carried out and a saline purgative is given the night before and again early the following morning. A very light breakfast is taken and two hours later the seeds are given in three portions, 2 hours apart. The patient should

remain in bed. If effective purgation does not occur within 3 hours of administration a dose of castor oil should be given. Experiments recently carried out on dogs to test the anthelmintic effects of the seeds gave inconclusive results. The seeds are sometimes taken three or four times a day for a few days until the worms are expelled. No toxic symptoms are produced even after large doses. Pumpkin seeds are used with great confidence by many physicians against tapeworms especially in the very young or aged, debilitated persons, and pregnant women. They are not so effective against the armed and dwarf tapeworms. Roundworms are also expelled. Pumpkin seeds are indicated in those cases of infestation where male fern, kousso, santonin, etc., are contra-indicated. Oil of pumpkin seeds is sometimes used instead of the seed but it is less effective.

Preparations.

Cucurbita semina præparata (B. P.). Dose 1 to 2 ounces (30 to 60 gm.) or more. **Oleum peponis** (N. O.) obtained by extraction with acetone, is a thick reddish-brown liquid. Dose $\frac{1}{2}$ to 1 ounce (15 to 30 gm.).

Cocoanut. The flesh and milk of the cocoanut, the fruit of a palm *Cocos nucifera* are said to have anthelmintic properties and to be specially effective against tapeworms. They have been largely used in India and other Eastern countries. When ingested in large quantities, the milk and the meat have a purgative action and are said to expel not only the worm but its head also. This, however, is doubtful. The patient usually fasts for 24 hours, drinks the milk and eats the meat of one whole nut; 2 to 3 hours later a purgative is given.

Musenno. The bark of *Acacia anthelmintica* or *Albizzia anthelmintica*, an Abyssinian tree belonging to N. O. Leguminosæ, is used as a tæniacide in Abyssinia. The bark is sold in flat pieces 5 to 10 inches long and is pale yellow in colour. It has an acrid taste and contains resins, an amorphous saponin-like principle *musennin* and an alkaloid *moussennine*. Two to four ounces of the powdered bark suspended in water or mixed with flour in the form of bread, or made into an electuary with honey are taken in the morning before breakfast. In Western medicine musenna is used in the form of an infusion in doses of 1 to 6 ounces, given in several portions and followed by a purgative. Moussennine has been isolated and given in doses of 3 to 4 grains (0.2 to 0.25 gm.).

Carbon tetrachloride. It has been shown to be an effective anthelmintic against tænia infections. See under carbon-tetrachloride.

CHAPTER III

ANTHELMINTICS ACTING ON NEMATODES

CARBON DERIVATIVES

This series of compounds is composed mainly of carbon and halogens. It was first suggested by Caius and Mhaskar that anthelmintic activity is correlated with the chlorine content and since chloroform shows a considerable anthelmintic efficacy against hookworm, some of the related compounds with higher halogen content may prove even more effective. Working on this hypothesis Hall (1925) tried carbon tetrachloride (CCl_4) as an anthelmintic with excellent results. Carbon tetrachloride has a marked anthelmintic effect against hookworms and its toxicity to animals is not very great. Owing to its low solubility and volatility and consequent slow rate of diffusion, comparatively small quantities are absorbed into the circulation. Large quantities can, therefore, be introduced into the alimentary canal without untoward effects. Other compounds related to carbon tetrachloride have also been tried. Ethylene dichloride or dichlorethylene ($\text{C}_2\text{H}_2\text{Cl}_2$) has been shown to be an effective anthelmintic against hookworms but it is distinctly weaker than chloroform and carbon tetrachloride; tetrachlor-ethylene (C_2Cl_4) is as effective against hookworms as carbon tetrachloride. Carbon trichloride or hexachlor-ethane (C_2Cl_6) is another of these compounds which has been tested but found ineffective. It is difficult to say, which are the factors responsible for the anthelmintic properties of these compounds. The chlorine content or chlorine concentration has been suggested as the explanation but a close study of the properties of these compounds seems to point to the physical factor of solubility.

CARBON TETRACHLORIDE

Carbon tetrachloride was discovered as long ago as 1849. It is chemically related to chloroform and this led Simpson

to try it as a general anæsthetic, but it was later on discarded because it failed to show satisfactory results. Hall (1921) found that it removed 100 per cent. of hookworms in dogs and recommended its trial in human beings. The drug is well tolerated in such doses as 4 to 6 c.cm., the only symptoms noticeable occasionally being dizziness, abdominal distress and vomiting. Further work has demonstrated beyond doubt the great efficacy of this drug in the treatment of hookworm infestations in man.

Chemistry and properties. Carbon tetrachloride is prepared from carbon bisulphide by direct chlorination in the presence of a catalyst such as aluminium chloride. It is also prepared by heating chloroform with iodine chloride at 165°C. when it is obtained free from contamination with sulphur compounds. It is a colourless non-inflammable liquid, having a disagreeable penetrating odour. Its specific gravity is 1.6, its molecular weight 153.8, and its melting point is -22.9°C., boiling point 77° to 78°C. It is only slightly soluble in water, freely soluble and miscible with chloroform, alcohol and other organic solvents such as petroleum, benzene, ether, fixed oils and essential oils. When shaken with milk it forms a good emulsion and this, especially skimmed milk, forms a good medium for its administration.

Impurities. Carbon tetrachloride often contains carbon bisulphide as an impurity, also traces of phosgene (carbonyl chloride) may occur. It is believed by some that these impurities, especially carbon bisulphide, greatly increase its toxicity. Strict standards of purity have, therefore, been recommended and a number of brands of the purified drug are on the market for medicinal use.

Pharmacological action. Carbon tetrachloride is a general protoplasmic poison. *Paramœcium caudatum* and free-living *amœbæ* are instantly killed in 1 in 3,000 dilution; movements of chilomastix cease in 1 in 4,000 dilution.

When applied to the skin carbon tetrachloride is a local irritant, specially when its evaporation is prevented. On mucous membranes it produces preliminary irritation followed by anæsthesia. When given by the mouth, it has a burning taste; there is a feeling of warmth in the stomach due to mild irritation of the mucous membrane. Reflex stimulation produces increased peristaltic movements of the stomach and intestine, and 1 to 2 hours after a large dose a stool may be passed. The drug passes through the stomach unchanged. That a certain amount is absorbed is evident from the fact that such symptoms as dizziness and sleepiness appear soon after ingestion. Absorption occurs through the lymphatics, especially when fatty substances are present in the gut. By this route, the drug goes straight to the systemic circulation without passing through the liver and a sufficient amount

may be absorbed to cause respiratory and cardiac depression. Absorption may also take place by the portal route, and when this is the main channel of absorption, such symptoms as jaundice, vomiting, bilirubinuria usually occur, due to the toxic effects of the drug on the liver. Both clinical and experimental evidence is conclusive that if carbon tetrachloride is given with alcohol or fatty substances its toxicity is considerably enhanced. When given with olive oil, cream and absorbable fats, animals quickly show signs of intoxication. Patients feel drowsy and have a desire to go to bed. These observations show the importance of controlling the diet when the drug is given. Fats should be excluded from the diet. With non-absorbable fats such as castor oil or liquid paraffin, the absorption is not so much increased, but it is preferable to discard fatty substances altogether. Large doses do not appear to be proportionately more harmful than small ones; in other words, the drug appears to have a tendency to protect against itself. Even small amounts such as 0.1 c.cm. dissolved in alcohol and given intravenously have a marked toxic effect on the heart and respiration, whereas after oral administration and injection into the mesenteric veins, these effects are negligible on account of the detoxicating action of the liver. In patients with cirrhosis where the liver parenchyma is damaged, severe toxic effects on the heart and respiratory system have been recorded.

Liver. If an injection of a fairly big dose of carbon tetrachloride is given into the mesenteric vein of an animal, there is acute destruction of the liver cells, and jaundice develops. When absorbed from the gut, the drug is taken to the liver and produces fairly generalised fatty degeneration; with larger doses, necrosis develops, usually beginning in the centre of the lobule and spreading to the periphery. The liver function test (phenol-red test) may show great derangement of function. In severe cases the hepatic cells at the periphery of the acini show widespread infiltration with droplets of fat. In cats after such small doses as 0.25 c.cm. per kilo. the liver tissue is practically all destroyed. This liver damage reaches its maximum in 48 hours, after which rapid repair sets in, and in a few days little evidence of damage is left. In therapeutic doses in man some injury to the liver in the form of fatty infiltration probably always occurs, and perhaps some slight fatty degeneration and central necrosis. But where the liver is originally healthy and due precautions are taken to avoid excessive absorption, this is not sufficient to disturb the normal functions of the liver nor to cause any permanent injury. Any damage to the liver which may result is rapidly made good if the drug is not repeatedly administered. Continued and prolonged administration of carbon tetrachloride in dogs produces cirrhosis of the liver. There is no evidence to show that the drug has any damaging effect on the pancreas.

Carbon tetrachloride has a depressing action on the heart and respiration. It slows the beats of the heart, the contractions become weak and the blood pressure falls. The amount of bilirubin is increased and calcium is decreased in the blood. After severe injury to the liver, guanidin and guanidin-like substances in the blood are increased and there may be hypoglycæmia. Administration of calcium salts is beneficial in this condition. It has been shown that acute intoxication is more likely to occur when the dietary calcium intake is reduced. The blood in these cases shows decrease of calcium content and there are convulsive symptoms resembling tetany. The administration of calcium chloride intravenously or calcium and parathyroid extract orally produces a rapid cure in experimental animals. It has also been shown that after severe injury to the liver there is definite retention of guanidine in the blood, bilirubinæmia and hypoglycæmia. In dogs symptoms of nervous irritability, gastro-intestinal irritation and hypoglycæmia can be produced by giving guanidine hydrochloride. When calcium is given to these animals the symptoms abate. The administration of ammonium chloride and hydrochloric acid also counteracts the toxic effects of carbon tetrachloride by increasing the ionised calcium of the blood.

The action of carbon tetrachloride on the nervous system resembles that of chloroform. Slight giddiness and a feeling of relaxation and drowsiness are the only symptoms noticed after therapeutic doses.

Next to the liver, the kidneys are the organs most severely affected in experimental animals. In dogs large doses produce cloudy swelling of the convoluted tubules and fatty infiltration. In cats the effects are much more severe. It is probable that the drug only reaches the kidneys in sufficiently high concentration to injure them if the liver is damaged and cannot adequately deal with it. Carbon tetrachloride is well tolerated by pregnant women. The drug relaxes the isolated uterus.

Excretion. Some of the drug is excreted in the feces unchanged; some is absorbed and is excreted through the lungs, in fact, these organs are the main channels of excretion whatever may be the mode of administration. Only traces are found in the urine. According to Robbins (1929) the drug is not excreted by the kidneys.

Dosage and method of administration. The dosage and method of administration have varied greatly in different hands. Though doses ranging from 1.5 c.cm. to 10 c.cm. have been tried by eminent workers, 3 c.cm. may be considered to be a safe dose for an average adult. Chopra and McVail (1923) employed a 60 min. dose of the chemically pure drug with excellent results and with no untoward effects. A single dose of 3 to 4 c.cm. is safer than a smaller quantity given in

divided doses, since by the latter method more of the drug is absorbed into the circulation. The anæsthetic protective action of the drug itself on the mucous membrane of the intestine is probably an important factor in limiting absorption.

The drug has been administered in various ways. Hall recommended that it should be administered in hard gelatine capsules. The capsule is usually of 1.0 c.cm. capacity and care should be taken before it is put in the mouth that it is covered tightly. It should be swallowed promptly to avoid the chance of inhaling the drug into the larynx and trachea, which may produce collapse or inhalation pneumonia. A simple method is to administer the drug in water with or without a subsequent dose of magnesium sulphate. The drug is poured in a tablespoon or a small glass and covered with water. As it is insoluble in water and very heavy it remains at the bottom and the patient gets water first, then the drug and then more water. Magnesium sulphate has also been used as a vehicle with success. The action of the drug is not impaired by simultaneous administration of salts though it is said by some to increase its irritant action on the intestinal mucosa. The saline purgative can be given either with the drug or one to two hours later. Simultaneous administration of a saline purgative does not reduce the anthelmintic activity of the drug as is believed to be the case with chenopodium. Chopra and McVail used skimmed milk as a vehicle. The drug forms a good emulsion with it, the disagreeable taste is to a large extent concealed and the toxicity is not increased. Given by this method carbon tetrachloride produces a high percentage of cures with one treatment, probably on account of more thorough distribution of the emulsified drug in the intestines.

There is no necessity for preliminary fasting with this drug. The patient takes his usual evening meal and takes carbon tetrachloride the next morning, no food being taken for three hours after. Administration of the drug, immediately before or after food is not advisable. No fat or alcohol should be allowed a few days before or after the treatment.

Anthelmintic effects. There is no doubt that carbon tetrachloride is the most effective drug known for the expulsion of

hookworms of the genus *Necator*. In doses of 3 to 4 c.cm. one treatment removes 95 to 98 per cent. of the worms and completely cures 60 to 70 per cent. of cases of pure necator infections. It is much less effective against ankylostomes and ordinarily does not completely cure more than 30 to 40 per cent. of cases though probably 80 to 85 per cent. of the parasites are expelled. The drug has little effect on ascaris. On oxyuris, carbon tetrachloride has a very decided action and large numbers of parasites are removed by a single dose of 3 to 4 c.cm. by the mouth. Its effectiveness cannot, however, be accurately measured as re-infections very commonly occur. Oxyuris infections can also be treated by enemata of 6 oz. of warm skimmed milk to which 6.0 c.cm. of carbon tetrachloride are added. The patient is generally given a strong dose of salts the previous night to empty the lower bowel and before the enema is given the foot end of the bed is raised and the patient lies on the left side. The parasites expelled are all dead. Trichuris and strongyloides are not affected. Tænia and hymenolepis are not destroyed in the dog but in man the drug is of great value in removing both *T. solium* and *T. saginata*. Maplestone and Mukherjee (1931) obtained a cure rate of 84.6 per cent. in a series of thirteen cases. The patients, on the day of admission, had a meal of milk and bread only and first thing the next morning they were given a dose of carbon tetrachloride, shaken up in a saline purge (saturated magnesium sulphate solution). Carbon tetrachloride would, therefore, appear to be a better drug than male fern for the removal of the tapeworms, though male fern has held the field for such a long time. Carbon tetrachloride is also effective in the treatment of fasciolopsiasis and has been used in combination with tartar emetic in the treatment of schistosomiasis.

Advantages of carbon tetrachloride over other anthelmintics are :—

- (a) A high degree of efficacy against hookworms.
- (b) No preliminary dietetic treatment is necessary except that fats and alcohol should be avoided a few days before and a day or two after the treatment.

(c) The patient need not remain in bed and thus need not be away from his usual work.

(d) The entire treatment can be given at one time.

(e) The cost is nominal, a dose of carbon tetrachloride costing only a few pice.

The last three points are specially important when dealing with large labour forces

Toxic effects. The only symptoms complained of in human beings after therapeutic doses of carbon tetrachloride are a sensation of warmth in the stomach, slight nausea, giddiness, confusion of thought and a feeling of mild alcoholic intoxication an hour or two after its administration. The patient has a taste of boiled cabbage in the mouth after eructations. Vertigo, cephalalgia and somnolence of a transitory nature may occur. A feeling of relaxation and drowsiness follows, and the patient may fall asleep. Rarely, there is an uncomfortable feeling in the epigastrium, followed by diarrhoea. When excessive absorption occurs or larger doses are given there is stupor, dilatation of the pupils and irregularity of pulse; jaundice may be produced and rarely pain in the lumbar region, hæmaturia and albuminuria. Death may occur from collapse and extensive lesions in the liver and the kidneys have been seen. Sometimes deaths have occurred with small doses such as 45 minims (3.0 c.cm.). In a million and a half cases treated in Fiji, there was one death in 50,000. All deaths occurred in alcoholics or persons heavily infested with ascaris, where mechanical obstruction leads to increased absorption. This danger can be overcome by prescribing the drug with chenopodium. The habitual use of alcohol and a damaged liver increase the susceptibility to toxic effects.

If symptoms of poisoning occur a brisk purgative should be administered. If liver damage has occurred only symptomatic treatment is indicated. If muscular irritability is present calcium might be useful in view of the fact that there is marked calcium deficiency in the blood following bilirubinæmia.

There is a good deal of controversy regarding the toxic effects produced by carbon tetrachloride. Some workers pronounce it as being very poisonous and are of opinion that

it should not be used under any condition. Others consider it to be a harmless drug. Clayton Lane (1930) cited fatalities with such doses as 1.5 c.cm. and considers that it is a retrogressive measure to use carbon tetrachloride in preference to thymol. He does not consider the drug safe for mass treatment. The author's experience is that if the cases are selected properly and necessary precautions are taken, carbon tetrachloride is a safe drug. Thymol is not only more expensive but is liable to produce toxic symptoms more frequently. Deaths have also been recorded after thymol administration for helminthiasis.

Precautions and contra-indications. The drug should be pure and the dose should not exceed 5.0 c.cm. The whole dose should be given at one time and not divided. It should always be accompanied or followed by a saline purgative. The drug is contra-indicated in badly nourished and weak individuals and those having a low calcium content in the blood. If anæmia is present give iron and arsenic or a course of liver extract. Under no circumstances should it be given when cirrhosis or other organic disease of the liver co-exists or when there is advanced kidney disease. A diet rich in carbohydrates, proteins and calcium is beneficial. It is better to administer the drug three hours after a moderate meal. Some recommend milk or calcium lactate for several days before taking carbon tetrachloride. Preliminary starvation is dangerous. A treatment with carbon tetrachloride should not be given for several days after chloroform anæsthesia and it should be given to alcoholic subjects with caution. Idiosyncrasy to carbon tetrachloride may exist and small doses may produce very marked toxic symptoms.

Carbon tetrachloride can be given to malaria and kala-azar patients, preferably during the afebrile period. It is well tolerated by pregnant women and children. When heavy ascaris infections are present, it should not be given alone but in combination with oil of chenopodium.

Carbon tetrachloride and chenopodium. A combination of carbon tetrachloride and oil of chenopodium is more effective than either of the drugs alone. The reason is not far to seek. Carbon

tetrachloride itself is effective against pure necator infections and chenopodium alone for ascaris infections, whereas ankylostoma infections are readily cured by a combination of the two with a relatively high proportion of chenopodium. The effects of the two drugs on the host are independent. One does not increase the toxicity of the other while their action is supplementary to each other as far as the parasites are concerned. Dilution of chenopodium with carbon tetrachloride lessens the discomfort of taking the former drug and reduces the cost of treatment. The dose of the two drugs is so reduced as to be below the toxic limit.

Different proportions of these two drugs have been combined by various workers. Smillie and Pessoa use 2 c.cm. of carbon tetrachloride with 1.0 c.cm. of oil of chenopodium or 0.5 c.cm. of ascaridol. Soper (1924) pointed out that the proportion of the two drugs should depend on the nature of the worms harboured. Chopra and Chandler (1929) recommend for predominantly ankylostoma infections, or where ascaris is abundant, 2 c.cm. of carbon tetrachloride and 20 min. of oil of chenopodium; when ankylostomes are less numerous than necators 3 c.cm. of carbon tetrachloride with 10 to 20 min. of chenopodium are preferable. A mixture of carbon tetrachloride and oil of chenopodium in proportion of 3 parts to one part is considered a safe and efficient anthelmintic against *T. saginata*. Daubney and Carman, in a series of thirty patients had a cure rate of 97 per cent. in what they described as light infections. Maplestone and Mukherjee, however, consider that carbon tetrachloride, by itself, given in a single dose, is as effective as the mixture.

Oil of chenopodium and carbon tetrachloride are readily miscible but the latter drug is more volatile and if the mixture is old the proportions will change. It is advisable to prepare it fresh. The disadvantage of this combination is that it is extremely obnoxious to take. Chenopodium can be given separately in a capsule, followed by carbon tetrachloride in water, salt or milk, either immediately or one or two hours after. When mass treatment is given the mixture is more convenient.

Preparations.

Carbon tetrachloride (U.S.P.X.) Synonym.—Tetrachlorethane. Commercial name—Necatorine. Dose 60 min. (3.0 c.cm.) as anthelmintic for adults.

Children of one year should be given 10 min., for a child of 10 years 30 min., and a youth of 16 years 40 min. Milk is the best vehicle for administration. Capsules of carbon tetrachloride are available containing 20 min. in each (P. D. & Co.) ; capsules of 0.3 c.cm., 1 c.cm., and 3 c.cm. are also marketed.

OTHER CARBON DERIVATIVES

It has already been pointed out that compounds of chlorine with ethane, ethylene, and methane series show anthelmintic properties and even compounds of the propane and butane series have been tried. Ethylene dichloride or dichlor-ethylene; $C_2H_4Cl_2$ is inferior to C_2Cl_4 which is as effective as CCl_4 . Carbon trichloride or hexachlorethane, C_2Cl_6 , is entirely ineffective; chloroform $CHCl_3$ has only slight anthelmintic action. It would appear that high solubility is correlated with increased absorption and consequent lowered anthelmintic action and increased toxicity. Very low solubility has the opposite effect and as the solubility becomes less and less the anthelmintic activity decreases. From our experience with these compounds it appears that solubility of something like that of carbon tetrachloride (1 in 1,250 of water) is the best from an anthelmintic point of view.

Chloroform. Chloroform is a well-known general anæsthetic, but it has been used very rarely internally except in small doses. The dose in the British Pharmacopœia is 1 to 5 minims, but as an anthelmintic as much as $\frac{1}{2}$ to 1 drachm (2 to 4 c.cm.) has been given. When administered in small doses and in a diluted form, its irritant action on the gastro-intestinal tract is not marked, the carminative and sedative action being more prominent.

Anthelmintic effects. As an anthelmintic, chloroform has been used either alone or in combination with other substances. It was used against tapeworm infections as early as 1897. Schultz (1911) tried it in hookworm infections of dogs with good results and suggested a mixture of chloroform and castor oil for use in man, but it did not prove to be very effective though many worms were expelled. The results on ascaris and whipworms were also not very striking. Chloroform in combination with oil of chenopodium is more potent than chloroform alone and has been shown by Caius and

Mhaskar (1923) to expel a high percentage of both ascaris and hookworms. A vigorous after-purgative is always necessary after its administration as most of the worms do not die but get benumbed and hence should not be allowed to recover from the stupefying effects of the drug. Chloroform used for internal administration must be of the purest quality, freed from all the common impurities such as hydrocarbons, chlorides, chlorine, free acids, phosgene, etc. The drug is no longer used as an anthelmintic since the introduction of more effective and comparatively less toxic carbon tetrachloride.

Toxic symptoms. These resemble the symptoms seen after carbon tetrachloride. Even 30 to 45 min. produce unpleasant symptoms and as the dose is increased beyond 45 min. the toxic effects become more marked. Dogs, after two doses of 3 c.cm. each, refuse food, vomit, are seized with mania-like symptoms, and die. Extensive changes in the liver are noticed in these animals, the lobules becoming yellow in colour and there is marked degeneration of the parenchyma, which shows mottling and there are hæmorrhages in lungs, stomach, intestines and diaphragm. In man the symptoms produced are those of gastro-intestinal irritation, but after absorption of large doses, drowsiness, loss of consciousness, coma, and death may occur. Fatty degeneration and central necrosis of the lobules of the liver occur, as in the case of carbon tetrachloride. Collapse and death may occur from severe gastro-intestinal irritation.

Eucalyptus oil and chloroform mixture. A mixture of eucalyptus oil and chloroform was introduced under the name of Manson's mixture. It contains eucalyptus 2 gm., chloroform 2 gm., and castor oil 40 gm. Most of the authorities who have tried this mixture agree that it is dangerous and not efficacious. Exclusion of eucalyptus from the mixture does not lower its anthelmintic efficacy showing that the main action is due to chloroform.

TETRACHLORETHYLENE

It is also known as perchlorethylene or carbon dichloride. It is an unsaturated chlorinated aliphatic hydrocarbon, having the formula, C_2Cl_2 . It is a heavy liquid, having a specific gravity of 1.6, boiling point varying between 110° — $120^{\circ}C$ and chlorine content of 85.5 per cent. It is very insoluble in water (1 in 10,000 or less). The drug is fairly stable in all climatic conditions, but it should be kept away from the air in well-stoppered amber bottles.

Pharmacological action. It is non-irritating and does not produce any local effect on the mucous membrane. Absorption of the drug,

when given by the mouth varies in different animals. Mice and rabbits show signs of narcosis when given in doses of 4 c.cm. per kilogram of body weight. Cats and puppies behave similarly but the effects are not so marked. Dogs can tolerate an enormous dose (10 c.cm. per kilo. body weight) without showing any signs of intoxication. Lamson and his co-workers (1929) in studying the absorption of the drug in dogs, puppies and cats stated that after injecting doses up to 10 c.cm. per kilo. into a loop of intestine, no tetrachlorethylene could be recovered from the expired air. Puppies however gave definite evidence of absorption; 4 c.cm. per kilo. raised the concentration of the drug to 3 to 6.3 mgm. per litre in the expired air in one and 3.2 to 4.7 mgm. in the other. Cats showed practically the same degree of absorption. Fatty substances or alcohol increase the absorption of the drug.

Blood pressure. When dogs are anaesthetised with excessive amounts of tetrachlorethylene or when it is given intravenously, it produces a marked fall in blood pressure and temporary cessation of respiration. If the same dose is given into the portal vein instead of the femoral, there is no fall in blood pressure, possibly because the liver fixes this substance. In man the dose of tetrachlorethylene being comparatively very small, *i.e.*, 2 to 3 c.cm., the effect on blood pressure is practically negligible.

Toxicity. Toxicity varies in different animals. Doses of 5 c.cm. per kilo. body weight kill rabbits in 10–20 hours. Mice can stand doses of 4–5 c.cm. per kilo. for nearly 10 hours before death ensues. In cats, doses varying from 5–10 c.cm. become fatal in 6–36 hours. In dogs, death occurs with doses varying from 10–25 c.cm. and doses below that are generally well retained without the appearance of any toxic manifestations. The pathological changes produced in the tissues especially of the liver and kidneys which are well-marked in chloroform or carbon tetrachloride poisoning, are very slight. This will depend on the rate of absorption from the intestine. Dogs do not exhibit any signs of liver necrosis or any change in the glomeruli or tubules of the kidney. The livers of cats and puppies may show a certain amount of fatty degeneration, depending on the amount of absorption of the drug.

As an anthelmintic. Hall and Shillinger (1925) were the first to investigate the anthelmintic properties of this drug. Judging from the promising results of experiments with a series of halogenated hydrocarbons in experimental animals, they considered tetrachlorethylene would be as effective as carbon tetrachloride in the treatment of hookworm disease, with the additional advantage of its lower toxicity. The efficacy of tetrachlorethylene as an anthelmintic, as in cases of other related compounds, depends upon the chlorine content. The efficacy is said to be increased with the amount of available chlorine. From this point of view, and also because of its being very

sparingly soluble in water the chances of absorption from the intestine are decreased. It has therefore been used in the treatment of human ankylostomiasis. The drug was found to be ineffective in human ascariasis. For trichuris infection tetrachlorethylene is considered to be superior to oil of chenopodium. Brosius, Peon and Carroll (1927) treated 24 cases of hookworm infection with tetrachlorethylene and obtained a cure rate of 91.7 per cent. They, however, observed toxic symptoms such as dizziness, epigastric pain, nausea, and vomiting in all but three cases. A combined treatment, 1.8 c.cm. tetrachlorethylene and 0.6 c.cm. oil of chenopodium, removed 94 per cent. necators and 48 per cent. ankylostomes.

Maplestone and Mukherjee (1933) concluded that tetrachlorethylene, used after the method described hereafter, is at least as efficient as tetrachloride, and it is safer than the latter on account of its not damaging the liver and kidneys when given in therapeutic doses. Another great advantage, especially when dealing with a large labour force, is the fact that alcohol does not increase its toxicity. The cure rate with tetrachlorethylene is probably slightly greater than with tetrachloride, as the dose given is larger (4 c. cm.) than the latter. This may explain the difference, but even if this is the explanation of the higher number of cures with tetrachlorethylene the practical advantage of it still remains, because if it can be safely given in larger doses than tetrachloride and cures more persons, it is a better drug for the purpose of treating hookworm infection.

Method of administration and dosage. No very special preparation is necessary before the treatment is started. The patient should be advised to take a light diet the evening prior to treatment and no breakfast is allowed on the day of treatment. The drug is given shaken up in two ounces of magnesium sulphate solution and the full dose for an adult is 3 to 4 c.cm. When combined with oil of chenopodium, the ratio should be 3 to 1, i.e., with 3 c.cm. of tetrachlorethylene 1 c.cm. of oil of chenopodium. Patients under sixteen years of age should receive a reduced dose.

The actual details of treatment as recommended by Maplestone and Mukherjee are as follows :—

Two ounces of saturated magnesium sulphate solution are placed in a flask or bottle of three or four ounces capacity and four c.cm. of

tetrachlorethylene and one c.cm. of oil of chenopodium are added to it. The flask is corked and shaken until the drugs are distributed throughout the mixture in the finest possible droplets; the dose is then given to the patient immediately, before the drugs have time to coalesce into larger drops and float to the surface, as will happen if the mixture is left standing. This method of shaking was adopted in the first place because it was stated that it was dangerous to give tetrachloride unless it was in finely divided droplets, and the same method has been continued with tetrachlorethylene because it is considered that the even diffusion of the drug throughout the draught gives it a much better chance of coming into contact with all the worms on the gut wall and is, therefore, more efficient than if given as an undivided globule of one drachm.

Toxic symptoms. Lamson and his co-workers (1929) fully investigated the relative toxicity of carbon tetrachloride and tetrachlorethylene on experimental animals and advocated the use of the latter in human ankylostomiasis because of its comparative safety. There has so far been no report of deaths with this drug and this is correlated with its low rate of absorption. Clinical observations, however, point to the fact that the drug is absorbed to some extent from human intestine, but not in amounts sufficient to produce damage of the kidney or liver cells. Kendrick (1929) reported only one case of grave intoxication in a total of 1,500 treatments; in this case there were signs of giddiness which developed into unconsciousness with twitchings of the whole body. Maplestone and Mukherjee (1929) observed varying symptoms of giddiness, vomiting or drowsiness in 8 out of 38 cases treated with tetrachlorethylene alone, and in 26 out of 37 cases treated with a combination of tetrachlorethylene and oil of chenopodium.

At present, from the results of clinical observations, it seems that tetrachlorethylene would be a very safe drug to employ as an anthelmintic and the danger of toxic symptoms can be avoided if alcohol and fatty substances are withheld during treatment.

Iodoform. Iodoform has occasionally been used for removing ascaris in man, in doses of 0.01 to 0.06 gm. three times a day in combination with sodium carbonate. Hall and Foster found this drug useless as an anthelmintic in dogs in much larger doses than those used in man.

CHAPTER IV
ANTHELMINTICS ACTING ON NEMATODES (Contd.)
THE ESSENTIAL OIL GROUP
OIL OF CHENOPODIUM

Synonyms: American worm seed, Mexican tea.

Chenopodium has been used as a household remedy against intestinal parasites for a long time. It was used by American Indians in the days of Columbus. The oil was originally used many years ago against ascaris, but was not popular because of the toxic and sometimes fatal effects produced in many cases. Schüffner and Verwoort (1913) tried it against hookworm in Sumatra in doses of 3 c.cm. in combination with castor oil and chloroform with excellent results. From that time the drug came rapidly into use. It came to the forefront during the Great War when the supply of anthelmintic drugs such as santonin and thymol was curtailed.

The active oil is obtained from *Chenopodium ambrosioides* var. *anthelminticum*, or the *American wormseed* belonging to the N. O. Chenopodiaceæ or the goosefoot family. A number of other species also yield the essential oil and *Herba chenopodia* is official in the Austrian Pharmacopœia. In India at least seven species of chenopodium grow, but only two of them yield oil having anthelmintic properties, these being *C. ambrosioides* and *C. botrys*. A variety of *C. ambrosioides* is cultivated in Java.

Chemical composition and properties. Chenopodium contains 40 to 80 per cent. of *ascaridole* which is chemically allied to essential oils; this is the anthelmintic as well as the toxic constituent. The oil has no definite boiling point and when it is heated to 100°C. in the air it explodes with violence. Different specimens differ much in their physical characters, the colour may vary from pale yellow to light golden yellow. The toxicity of different stocks also varies greatly and the samples met with in the market are often adulterated up to the extent of 50 per cent. The whole oil as well as ascaridole are practically insoluble in water and are very slightly absorbed; on this quality its anthelmintic action is chiefly dependent. Ascaridole is

altered by heat into a less volatile substance which has much weaker anthelmintic properties. Distillation should therefore be carried out with great care.

Besides the volatile substances chenopodium also contains certain terpenes—limonene, cymene and terpinene. Specimens of chenopodium oil met with in commerce vary a great deal in activity on account of variations in their ascaridole content. The drug now on the market is properly standardised.

Pharmacological action. Oil of chenopodium like other volatile oils is diffusible and irritant to the skin and mucous membrane. It has germicidal properties. It kills protozoa and was at one time recommended in amœbic dysentery. Internally the oil has a sharp burning taste, produces salivation and reflexly stimulates the flow of gastric juice. The peristaltic movements of the intestines are decreased and a constipating effect is usually produced. Large doses produce severe irritation of the whole of the gastro intestinal tract. The oil is absorbed from the stomach with difficulty, but absorption may take place from the intestines.

The oil has a markedly depressant action on the circulation, the blood pressure shows a considerable fall in experimental animals after intravenous injections of 0.02 c.cm. per kilo. The pulse becomes slow and weak; there is also marked depression of respiration.

The oil has a well marked effect on the central nervous system. There is at first a transitory stimulation followed by a marked depression of the respiratory, cardio-vascular and other centres in the medulla. Later, the higher centres are affected, giving rise to stupor and coma. The special senses, especially sight, may be affected. Cases of blindness and deafness have been reported after use of chenopodium oil.

Whether given by the mouth or intravenously the oil is partly excreted by the lungs and partly by the kidneys. The elimination is slow and neither the oil nor the products of its decomposition can be readily detected. Small doses have a diuretic effect by mildly irritating the kidneys; large doses may set up inflammation and albuminuria. Subcutaneous injections of the oil in animals set up renal irritation.

In vitro experiments show that the action of the oil is probably due to penetration through the cuticle and into the cells of the parasites, resulting first in stimulation and then paralysis of the musculature. In such dilutions as 1 in 10,000 to 1 in 5,000 there is at first tonic contraction of the muscles of ascaris, followed by relaxation and paralysis, so that the parasites cannot resist the intestinal peristalsis. Experiments on earthworms show that the toxic effect is much greater at 37°C than at 21°C.

Anthelmintic effect. Oil of chenopodium has a marked action on all kinds of intestinal nematodes, but little or no action on large tapeworms. It is particularly effective against ascaris

and is as good an ascaricide as santonin, a very high percentage of worms being removed even if a complete cure is not effected. The drug does not kill the parasites but only paralyzes them, and they must be expelled by free purgation. Against hookworm infection chenopodium is a particularly useful drug. It is less effective against necators than carbon tetrachloride, but is about equally effective against ankylostomes. In doses of 30 min. it can be depended upon to remove about 90 to 95 per cent. of necators and about 80 to 85 per cent. of ankylostomes.

The oil is not so effective against trichuris because of the situation of these worms in the colon and cæcum. Large numbers of threadworms are expelled but here also the effectiveness is less than on the worms situated higher up in the gut. Carbon tetrachloride is probably more effective against these worms. Its anthelmintic efficacy against clonorchis, hymenolepis and strongyloides is doubtful. Intramuscular injections of chenopodium or ascaridole are said to be useful in filariasis, the initial dose being 0.5 c.cm. gradually increased to 2.0 c.cm. Injections are said to cause disappearance of filaria in many cases.

Dosage and method of administration. The maximum dose of the oil is 3 c.cm. given in three doses of 1 c.cm. each, at intervals of an hour. The last dose is followed one hour later by an ounce of saturated solution of magnesium sulphate. This dosage cannot be adopted in general treatment, because it frequently gives rise to severe toxæmia especially in ill-nourished patients.

Most of the authorities recommend 1.5 to 2.0 c.cm. (30 min.), divided into two or three doses, given at intervals of one hour. This method is both safe and efficient. Doses recommended for children are, 3 capsules of 2 min. each for a child of 3, 3 min. each for a child of 5, 5 min. each for a child of 10 and 7 min. each for a child of over 12 years. Weak individuals should have reduced doses, according to their state of health.

The drug may be given in the morning in doses of 10 to 15 min. at 7, 8 and 9 a.m. Some authorities allow an interval of 2 to 3 hours between the doses and some prefer to give the anthelmintic and purgative together, 10 to 20 drops being given

with senna or mixed with castor oil. To conceal the taste it may be mixed with olive oil or almond oil.

Pure ascaridole is now on the market and is used in doses of 1.0 c.cm. for an adult given in 2 or 3 divided doses an hour apart. Pessoa (1923) gave 1.0 c.cm. in one dose in hard gelatine capsules on an empty stomach, followed by a saline purgative half an hour later; a preliminary purgative is not necessary. For children up to 5 years, 1 to 2 drops of ascaridole in an emulsion of 10 to 20 c.cm. of castor oil is the best. For children between 6 and 15 years, one drop for each year of age in gelatine capsules followed an hour later by a saline purgative is generally recommended.

Chenopodium has a very obnoxious and nauseating taste and is preferably given in hard gelatine capsules, although it can be taken in syrup or in a lump of sugar. The results, obtained when given in the form of emulsion, are inferior to those when the oil is given by itself. It has also been shown that the drug is less toxic and its anthelmintic effects are not only as good but better if no preliminary dietary measures are adopted and no pre-purgative is given. This makes the oil a useful drug for labour forces in the field. It is preferable to give the oil three hours after a moderately light morning meal.

Necessity of a purgative. A post-purgative should always be administered after chenopodium. It has been pointed out that chenopodium inhibits intestinal peristalsis and thereby tends to produce constipation. The administration of castor oil immediately after it retards the absorption of the drug and helps its elimination from the alimentary canal. Certain fixed oils such as olive oil prevent the toxic effects of chenopodium. If a saline purgative is to be used it should be given at least 2 hours after administration of the oil as it has been shown that simultaneous administration of salts greatly reduces the anthelmintic efficacy of the drug.

Chenopodium has been tried intramuscularly and is said to have an anthelmintic effect when given in this way. The mixture prescribed for this purpose consists of chenopodium oil 60 c.cm., camphorated oil 60 c.cm. and resorcin 4 gm. The usual dose is 4 c.cm. of the mixture injected into the buttock. Its vermifugal action against hookworm is

small but is quite efficacious against trichuris. Intravenous injections of the oil in doses of 2.0 c.cm. have been given, with the idea that after absorption into the blood the oil will reach the hookworms, which have anchored themselves to the mucous membrane and which will then let go their hold. Given in this way the oil may produce a mild collapse.

Toxic effects. The oil of chenopodium is a toxic substance and causes severe irritation of the mucous membranes. Rabbits die of vomiting, convulsions, coma and paralysis after 0.5 c.cm. doses; 0.25 c.cm. per kilo. is fatal in cats. Fish die in dilution of 1 in 8,000 in water and are narcotised in 1 in 25,000. A full dose in an animal if repeated within a few days may cause death, and sensitiveness to the oil persists for at least 5 to 9 days. This should be remembered when treating unsuccessful cases in man. In man it sets up severe gastro-intestinal irritation; such a dose as 3 c.cm. produces nausea, vomiting, severe abdominal pain and finally paralysis of the gut. A certain amount of dizziness is nearly always present and there may be slight deafness and ringing in the ears. After excessive doses extreme dizziness, a feeling of intoxication, prostration, headache, drowsiness and unconsciousness occur, showing that there is severe toxæmia. The face is flushed, respiration slow, pupillary reaction sluggish and convulsions may follow giving place to flaccid paralysis. Albuminuria is present in severe cases and there may be hæmaturia. Autopsy shows severe inflammation of the gastro-intestinal tract, liver, and kidneys, and hyperæmia of the brain; there are fatty changes in the parenchyma of the liver and the kidneys. Deafness may sometimes persist. Children are more susceptible to the effects of the oil than adults and it is advisable not to exceed the prescribed dosage. It is better to use some other anthelmintic in children under 5 or 6 years of age and in very old and debilitated individuals. Owing to its slowness of absorption the toxic symptoms may appear a day or so after administration, and cumulative effects may be produced by smaller doses several days apart. In man death has been reported from ingestion of half an ounce or even less. Tolerance is decreased by starvation and debility, and increased by fixed oils.

Treatment of poisoning. As soon as inordinate sleepiness and depression or any other symptoms of intoxication appear, the administration of the drug, if all the capsules have not been given, should be stopped and a brisk purgative given. The stomach should be quickly washed out. There is no antidote known and the treatment is, therefore, entirely symptomatic. Respiratory and cardiac stimulants should be given.

Precautions and contra-indications. Chenopodium oil should be given with caution and in small doses when disorders of the heart and kidneys are present. It is forbidden in chronic nephritis and organic disease of the heart, and where hepatic and gastro-intestinal disorders are present. Prior to the administration of chenopodium against hookworm it is better to administer iron and arsenic and liver extract, especially when the patients are anæmic.

Preparations.

Oleum chenopodii (U.S.P.X.). It is distilled with steam from the fresh above-ground parts of the flowering and fruiting plant of *Chenopodium ambrosioides*. Dose 10—30 min. (1 to 2 c.cm.); for children as many minims as the number of years up to 10 years.

Ascaridole (N. O.). Dose 10 c.cm. A synthetic ascaridole has been prepared which in doses of 4 drops for each year of age of children and 70 drops for an adult is an effective anthelmintic.

OTHER ESSENTIAL OILS USED AS ANTHELMINTICS

A number of essential oils have been used in the treatment of intestinal worms but none of them have any specific action against any of the parasites.

Oleum eucalypti. The oil is distilled from the leaves of *E. globulus*, *E. dumosa* and a number of other species. The chief constituents of the oil are pinene, eucalyptol (cineol) and aldehydes of fatty acids. It has been used as an anthelmintic in combination with chloroform but its action appears to be very mild. Caius and Mhaskar (1920) gave it in 40 min. doses in the form of a mixture with gum acacia and castor oil. Doses of 60 min. and over produced giddiness, and vomiting, probably owing to the presence of aldehydes. It was quite ineffective against hookworms and had little or no effect against ascaris and whipworms. Pure eucalyptol has also been tried; it is much less toxic but the vermifugal action against intestinal parasites is feeble.

Oleum cajuputi. Cajuput oil is a volatile oil distilled from the fresh leaves and twigs of *Melaleuca leucadendron*, var. *minor*, *M. viridiflora*. It is a green-coloured oil with an aromatic odour and a pungent taste. The chief constituents are: cajuputol, which is the same as eucalyptol or cineol, terpineol, small amounts of pinene and traces of aldehydes. The oil has, therefore, the same active principles and same action as oil of eucalyptus.

It has been used as an anthelmintic in the gold mines of Guiana in the treatment of mild hookworm infections. Caius and Mhaskar (1920) tried the oil and found that even in 60 min. doses (the maximum tolerated dose) hookworms were very feebly affected and ascaris and whipworms were not attacked at all. The oil of cajuput cannot, therefore, be recommended as an anthelmintic.

Oleum terebinthinae. Common turpentine is an olcoresin obtained from several varieties of pines, chiefly from *Pinus palustris*. There are several varieties of turpentine oil on the market but the rectified oil is the only variety used for pharmaceutical purposes. Pure oil is a colourless liquid chiefly composed of one or more terpenes. Its anthelmintic dose is $\frac{1}{2}$ to 4 drachms, usually combined with castor oil. **Hausius terebenti** is sometimes prescribed; it consists of the oil combined with a drachm of glycerine and an ounce of cinnamon water.

Oil of turpentine is irritant to the skin and mucous membrane. It is readily absorbed from the alimentary canal and circulates in the blood unchanged. It is excreted through the skin and lungs but mainly through the kidneys, partly unchanged and partly as terpenols in combination with glycuronic acid.

Oil of turpentine is a toxic drug and half an ounce has proved fatal in children. In larger doses in adults severe gastro-intestinal irritation is set up, followed later by acute nephritis and painful micturition. The medullary centres are stimulated, producing at first excitement, delirium, and convulsions and later paralysis. Pain in the chest due to bronchitis is set up by irritation of the respiratory passages. If symptoms of poisoning occur the gut should be evacuated by large doses of magnesium sulphate; stimulants such as coffee should be administered.

As an anthelmintic, the oil of turpentine in doses of $\frac{1}{2}$ to 1 ounce has been successfully used in man. Some authorities have discouraged its use on the ground that it is likely to produce nephritis during excretion. In large doses, as used for expelling worms, it acts as a purgative and is not absorbed in sufficient quantities to cause renal irritation. Tapeworm infestations have been treated with one ounce doses in combination with castor oil with satisfactory results. Caius and Mhaskar (1920) treated a series of cases of hookworm with oil of turpentine, but the results were disappointing. All the evidence is, therefore, against its use as an anthelmintic except possibly for tape-

worms. Saline or soap enemata containing an ounce of turpentine are effective in expelling oxyuris.

Oleum tanceti (Tansy.) This oil is distilled from the flowering tops and leaves of tansy, *Tanacetum vulgare* belonging to N. O. Compositæ. It is a yellowish brown liquid consisting of thujone, borneol, camphor and a number of resins. It has been tried as an anthelmintic but is found to be wholly ineffective against hookworm, ascaris and whipworms. It is also a toxic drug and even in therapeutic doses produces vomiting and giddiness. The leaves and tops of *Tanacetum vulgare* have been used in the form of an infusion or as an enema to expel ascaris and oxyuris.

Oleum absinthii. The oil of absinth or vermouth or wormwood is obtained from the flowering tops and leaves of *Artemisia absinthium* belonging to N. O. Compositæ. It is usually a dark green oil consisting of a number of volatile principles and a bitter substance called *absinthin*. Medicinally absinth was chiefly used as a febrifuge and as an anthelmintic. It is a fairly toxic drug and is seldom used at present. The oil was tried by Caius and Mhaskar (1920) in the form of an emulsion against hookworms but the results obtained were not encouraging.

Oleum caryophylli. The oil of cloves is a thick yellow oil distilled from the flower buds of *Caryophyllus aromaticus*. The chief constituents of this oil are an unsaturated phenol called *eugenol* which forms 80 to 90 per cent. of the oil, acetyl derivative of eugenol (2 to 3 per cent.), caryophyllene, etc.

The oil has been tried against hookworms with little success. Cairns and Mhaskar (1922) by using an oil containing 92 per cent. eugenol in the form of an emulsion obtained satisfactory results. With 90 min. doses, administered in divided doses at half an hour intervals, 64.3 per cent. of hookworms were expelled, necators being much more vulnerable than ankylostomes. Oxyuris are also expelled in large numbers; ascaris and trichuris are not affected.

Pure eugenol and iso-eugenol have also been tried and found to have well marked vermifugal action against hookworms, their action resembling thymol. Both are well tolerated in doses of 1 to 1½ drachms, and with such dosage they produce a mild purgative effect, thus obviating the necessity for an after purgative.

Oleum betulæ. Betel oil is an essential oil obtained from the Indian betel vine commonly known as 'pan'. Leaves of this plant contain 30 to 70 per cent. of phenols consisting mainly of eugenol mixed with a small percentage of betel phenols. The oil in doses ranging from 30 to 90 min. has only a weak anthelmintic action against hookworms, expelling less than 20 per cent. of these parasites. The other intestinal parasites are not touched. The popular belief regarding the anthelmintic effect of betel chewing can be accounted for by the

elimination of immature hookworms from the body by constant spitting and so preventing them from migrating from the trachea into the oesophagus.

Oleum sassafras. The oil of sassafras is an essential oil distilled from the root of *Sassafras venifolium*. It contains 85 per cent. of safrol and has powerful antiseptic properties resembling those of clove oil. According to Cairns and Mhaskar a dose of 30 to 60 min. expels 52.4 per cent. hookworms; other intestinal parasites are not affected. The oil resembles chenopodium oil in its action, but it is much less toxic to the host. Pure safrol has also been used in 60 min. doses and has been found a fairly good anthelmintic against hookworms.

Oleum anisi. This is obtained from distillation of ripe fruit of *Pimpinella anisum*. The oil is mainly composed of anethol but also contains small quantities of terpene. Its action closely resembles that of thymol. It is a fairly good vermicide, the maximum dose of 60 min. expelling about 50 per cent. of hookworms.

Pure anethol has also been used and is quite effective against hookworms expelling as many as 70 per cent. of the parasites. No toxic symptoms are met with either with the oil or with the active constituent anethol, even in one drachm doses.

Oleum cinnamomi. The oil is derived from *C. zeylanicum* and it contains large quantities of cinnamic aldehyde (50 per cent.) and is a powerful germicide. The oil has been tried but with disappointing results against ascaris, trichuris or hookworms.

Oleum rutæ. The oil is derived from the fresh leaves of common Rue, *Ruta graveolens*. It was used as an anthelmintic in India and is still used in some parts, the juice of the plant being given to children to expel intestinal parasites. Its anthelmintic efficacy is, however, slight.

Oleum copaiba. It is quite useless as an anthelmintic even in doses of 30 to 60 min. against ankylostomes, necators, ascaris and trichuris.

CHAPTER V

ANTHELMINTICS ACTING ON NEMATODES (*Contd.*)

SANTONIN

Santonin is a classical remedy for the treatment of ascaris and oxyuris infections. It is obtained from *Artemisia maritima*, a plant whose flowering tops were used by the ancient Greek and Roman physicians as a remedy to expel intestinal parasites. Santonin is one of the most expensive drugs. Before the War practically the whole of santonin supply of the world came from Russian *Artemisia cina*. A number of allied species such as *A. maritima*, var. *stechmanniana* and *A. pauciflora* (*A. anthelmintica*) also grow in Turkestan. Owing to political and economic disturbances in Russia some years ago there was great scarcity of santonin, and *A. cina* having good santonin content was successfully cultivated in Holland. *A. maritima* or *A. brevifolia* grows abundantly in a state of nature in the dry inner valleys of the western Himalayas from Kumaon to Kashmir at an altitude of 4,000 to 12,000 feet above the sea level, and recently santonin has been obtained on a commercial scale from this source. Large quantities of artemisia with high santonin content are found to grow wild in the Kurram valley in the North-Western Frontier not far from the railway line.

Chemical composition and properties. The active principles of *A. maritima* are :—(1) A neutral principle, santonin which is responsible for the anthelmintic properties, (2) a bitter principle, artemisin (oxy-santonin) which is not very active, (3) a volatile oil, and (4) santonic acid. The amount of santonin extracted from the Russian *Artemisia* is usually 1.2 to 1.4 per cent., but may be as high as 2.3 to 3.6 per cent. The yield from the artemesia growing in Kashmir does not exceed 1.0 to 1.5 per cent. and the yield from that of Kurram Valley is slightly less. Santonin is a crystalline anhydride or lactone of santonic acid; it occurs in colourless, shining, flattened, rhombic prisms or as white crystalline powder. It is stable in the air, but on exposure to light develops a yellow colour due to the formation of an isomeride of santonin called chromosantonin.

Pharmacological action. Externally santonin has very little action. Taken by the mouth, it is tasteless at first but develops a bitter taste after a short time. Santonin, unlike most other anthelmintics is not

a gastro-intestinal irritant. It is quickly absorbed from the empty stomach. In the small intestine, the drug is acted on by the alkali present, sodium santoninate being formed. The sodium salt is soluble and is absorbed, but its effect on the circulatory and respiratory systems is slight in therapeutic doses. With large doses the symptoms produced are chiefly due to involvement of the central nervous system which is first stimulated and then paralysed. The special senses are usually affected most, and anomalies of vision and colour perception are commonly produced. At first white objects appear bluish, this is soon followed by xanthopsia or yellow vision which may persist for a few days and then disappear; blue seems green and violet is scarcely perceived. The usual dose producing these symptoms is 0.2 gm., the effect being probably on the cranial nerves. Smell, taste and hearing are sometimes affected. When large quantities of santonin are absorbed, twitchings and epileptiform convulsions, resembling those occurring in strychnine poisoning, are produced. In man convulsions rarely occur, but they are common in the dog and the rabbit. The animal usually dies of asphyxia from stoppage of respiration. Santonin is chiefly eliminated in the urine partly unchanged and partly in the form of oxysantonin which gives the urine and sometimes the faeces a deep yellow color. This colouration resembles that produced by anthracene purgatives, such as rhubarb, whose active principles are excreted in the urine. The two can be differentiated by the fact that by shaking the urine with a little lime water or barium water the santonin colouration remains in solution while the anthracene bodies are precipitated. Elimination of santonin begins quickly, but may go on for several days.

In vitro, ascaris are not killed even by saturated solutions of santonin in olive oil or castor oil. The parasites, however, become irritated and try to escape from the proximity of the drug. The irritant effect of the drug causes the parasites to move about in their efforts to escape, thus driving them into the colon whence they are expelled by a purgative. This irritant action can also be seen on the muscle tissue of leeches and worms; it is specific and is probably due to the presence of the lactone group though some believe that the anthelmintic action is in no way correlated with the structure of the lactone. It is not produced by santonic acid and is not apparent on the muscles of the vertebrates. The presence of dilute bile and alkali appears to increase markedly the toxic action of santonin on the parasites.

Santonin as an anthelmintic. Santonin is considered the most effective drug against ascaris, with the possible exception of oil of chenopodium. It is useless in intestinal taeniasis. Santonin acts best when combined with 3 or 4 grains of calomel and followed by a saline purgative six hours later. Calomel stimulates the flow of bile which enhances the toxic action of

santonin on the parasites. Santonin is best prescribed in the form of a powder either as coarse crystals or as trochisci. In the form of coarse crystals as ordinarily sold it is preferable to the finely divided powder, as the latter is liable to produce toxic symptoms. Alkalies dissolve it forming soluble alkaline santoninates which are usually absorbed rapidly, and therefore this combination should be avoided.

In determining the dosage for children a good rule is to give $1/6$ grain for every year of age; for adults 1 to 5 grains according to the general constitution of the patient may be given. The preliminary preparation of the patient and after-purgative are most important considerations in santonin administration. The following procedure has been used successfully at the Calcutta School of Tropical Medicine:—

The patient is given his last meal at 5 p.m., no food being allowed after that. In severe infections it is advisable to keep the patient on light diet for 24 hours previous to administration of the drug. At 10 p.m. 3 grains (0.2 gm.) of santonin combined with 3 to 5 grains (0.2 to 0.3 gm.) of calomel are given. At 6 a.m. the following morning, $\frac{1}{2}$ to 1 ounce saturated solution of magnesium sulphate or sodium sulphate is given. The stool should be examined for 72 hours after treatment and should be re-examined about 10 days later; if negative the patient may be considered cured.

As a rule no symptoms are observed, but nausea followed by vomiting may be produced. By using the above method 18 out of 19 cases were cured in one series. Santonin is a poisonous drug and idiosyncrasy to the drug is common. It is, therefore, recommended to give $\frac{1}{3}$ or $\frac{1}{2}$ of the total dose the first time and if no sensitiveness is shown the drug may be repeated.

Some authorities give santonin combined with an equal or larger doses of calomel every morning for 2 or 3 days in succession and repeat the process every 3 or 4 days as long as eggs are found. This procedure is likely to lead to toxic effects. Some observers consider it inadvisable to use an oily purgative such as castor oil with santonin, as it is likely to increase absorption; others consider that it inhibits absorption.

Combination of santonin and chenopodium. Maplestone and Mukherjee (1931) reported very encouraging results by combining santonin with chenopodium in the treatment of roundworm infestations. The method employed by them consists in the administration of 5 grains (0.3 gm.) of santonin in powder form and 1 c.cm. of oil of chenopodium in a capsule at the same time. A saline purgative is given after two hours. According to these workers santonin cures 60 per cent. of adult and 48.2 per cent. of children and the figures for combined treatment (santonin and oil of chenopodium) are 92.3 per cent. and 54.8 per cent. respectively.

Santonin is a toxic drug and should on no account be prescribed unless the diagnosis is made by thorough examination of the stools. The practice of prescribing santonin on the mere assumption of parasitic infestation is to be deprecated.

Subcutaneous, intramuscular and intravenous injections of 'santonin-sodium' have been successfully tried against ascaris.

Other uses of santonin. Santonin in doses of 3 grains for three days has been used in the treatment of amœbic dysentery and sprue, the yellow santonin being specially recommended in the latter condition. It has also been used in long-standing cases of diabetes associated with nervous disturbances particularly numbness of the extremities and pain of the sciatic or brachial plexuses. Such pains are sometimes relieved by such minute doses as 1/60 grain (0.001 gm.) or less, three or four times a day. The urinary sugar may diminish and the nervous symptoms abate with doses of santonin gradually increased from 3 grains (0.2 gm.) to 10 grains (0.6 gm.) daily. Patients susceptible to the drug should be previously tested by giving $\frac{1}{4}$ grain (0.03 gm.) and it should not be continued for more than 10 days. Santonin also relieves the lightning pains of *tabes dorsalis* the initial dose for this purpose being 1/120 to 1/60 grain (0.5 to 10 mgm.). It has been used in the treatment of epilepsy in doses of 2 to 5 grains (0.12 to 0.3 gm.). In small doses of 1/60 to 1/6 grain (1 to 10 mgm.) it has been recommended in the treatment of retinitis, amblyopia, and colour-blindness on account of its stimulant action on the retinal nerves.

Toxic effects. Toxic manifestations are usually evident when the drug is rapidly absorbed and these, in their turn, depend on the conditions of the alimentary tract favouring or retarding absorption. Children are more susceptible and the fatal cases reported are entirely among infants. Adults as a

rule are not seriously affected by doses less than 7 or 8 grains (0.5 gm.). In infants under 3 years, death may occur with a one grain dose ; the drug should therefore be used very cautiously in them. Repeated use of the drug is known to lead to tolerance.

Symptoms of santonin poisoning vary from slight manifestations of anomalies of vision to convulsions, coma and death. In mild poisoning digestive and ocular disturbances alone are observed, but in severe cases disturbances of the central nervous system predominate. Headache, vertigo, mental confusion, hallucinations, weakness, profound prostration, somnolence passing on to unconsciousness may develop. The diarrhoea is often profuse and the stool may contain blood; convulsions, coma and death may follow. The heart becomes slow and feeble and there may be syncope from the fall of blood pressure due to depression of the heart and dilatation of the blood vessels. The kidneys and urinary passages are irritated producing painful micturition, albuminuria and hæmaturia. Tremors, spasms of muscles, and loss of speech have also been noticed.

Treatment of poisoning. This consists in rapid and thorough emptying of the bowels by purgatives and an enema. A central emetic like apomorphine may be given. Stimulants such as atropine, caffeine, or camphor, may be administered, and the patient kept warm. If convulsions are present repeated doses of chloral hydrate or inhalations of chloroform or ether may be tried. If respiration fails, artificial respiration should be resorted to.

Precautions and contra-indications. It is advisable not to give santonin on an empty stomach as it is soluble in the gastric juice and may be absorbed. It is preferable not to give it with an oily cathartic. Fever is not a contra-indication to the administration of this drug.

Preparations.

Santonica with a santonin content of 1.5 to 3 per cent. is used in $\frac{1}{2}$ to 1 drachm (2 to 4 gm.) doses as an anthelmintic.

A combination of santonin and bile called **santonin bile** has been prepared but it may produce toxic symptoms from rapid absorption

Santoninum. Dose 1 to 3 grains; U.S.P. dose 1 grain (0.06 gm.); in the French Codex $1\frac{1}{2}$ grains as a single dose, the maximum dose given during 24 hours being 5 grains. **Chromosantonin** (N.O.) or golden santonin is a modification of ordinary santonin formed by exposure to sunlight. The dose is the same as ordinary santonin and it is stated to be useful in sprue and dysentery. **Trochiscus santonini** contains 1 grain in each. Dose 1 to 3. **Trochiscus santonin Co.** contains $\frac{1}{2}$ grain of santonin and calomel each. Dose 1 to 2 grains.

Confectio santonini Co. containing santonin in combination with ginger, jalap, sulphur and senna is used in some of the children's hospitals.

Haustus santonini et olei ricini, contains 4 grains of santonin, half an ounce of castor oil, half an ounce of mucilage and peppermint water. It is prescribed on an empty stomach but symptoms of poisoning may occur.

Sodii santoninas. Dose 1/50 grain (1 mgm.) cautiously increased to 1/20 or 1/10 grain (3 to 6 mgm.) is used for systemic effects. As an anthelmintic 1/4 to 1 grain for adults preferably in salol-coated pills.

Calcii santoninas (N. O.). Dose 1 grain. It is a white tasteless insoluble powder.

Artemisine in doses of 1/600 grain (0.0001 gm.) has been used as a gastric stimulant.

CHAPTER VI

ANTHELMINTICS ACTING ON NEMATODES (*Contd.*)

THYMOL AND ALLIED COMPOUNDS

A number of compounds belonging to the stearoptene group, including menthol, borneol, camphor, and thymol have been tried as anthelmintics but only the last-named is effective. Caius and Mhaskar (1924) showed that so far as these compounds are concerned, (a) the hydrogenation of benzene decreases their anthelmintic action, but increases their toxicity to the host, (b) the total destruction of the benzenoid structure leads to the formation of toxic compounds with no anthelmintic properties, (c) esterification of the phenolic hydroxyl group leads to formation of non-anthelmintic and non-toxic compounds, e.g., thymotal.

THYMOL.

Thymol was first tried in the treatment of hook-worm infections by Bozzolo in 1879. Since then it has been extensively used with satisfactory results. In recent years, however, oil of chenopodium and carbon tetrachloride have largely supplanted this drug, for they are more effective and less dangerous than thymol and can safely be used for mass treatment and labour forces.

Thymol or thyme camphor is contained in a number of essential oils from many plants, the chief amongst which is *Thymus vulgaris*, an evergreen shrub belonging to the Labiatae family. In India thymol is manufactured on a commercial scale from *Cuminum cyminum* which contains large quantities of cumin oil whose chief constituent is cumin aldehyde which can be readily converted into thymol. The oil of *Carum copitum* known as oil of *ajowan* also contains not less than 40 to 50 per cent. of thymol. The oil from *Monarda punctata* growing in America contains 60 per cent. of thymol and *Origanum hirtum* growing in Crete contains 60 to 67 per cent.

Chemistry. The chemical formula of thymol is methyl-isopropyl-phenol and it is a stearoptene. It is a higher homologue of benzene. It occurs in large transparent crystals, slightly soluble in water (1 in 900) but freely soluble in fats, oil and alcohol. When it comes in contact with menthol, chloral, camphor, etc., it liquifies them.

Pharmacological action. The action of thymol is similar to that of phenol; it has about one fourth the antiseptic power of phenol and in concentration as low as 1 in 10,000 kills free-living protozoa such as paramoecia. It is fatal to staphylococcus aureus in 0.5 per cent. concentration, to typhoid and anthrax bacilli in 0.8 per cent. and pneumococcus in 1 per cent. Growth of putrefactive bacteria is prevented by 0.1 per cent. solution and 1.0 per cent. is required to kill them. It inhibits the growth of moulds in 0.02 per cent. solution.

Externally thymol has no action on the unbroken skin but it can exert its caustic or irritant action on mucous membranes. When taken internally in ordinary anthelmintic doses, it produces a feeling of well-being and comfort in the stomach; there is reflex stimulation of the peristaltic movements of the intestines. The presence of fatty constituents in the intestines promotes absorption of thymol and if this absorption is large it gives rise to systemic effects and may produce fatty degeneration of the liver. It is, therefore, advisable to avoid fats, alcohol, glycerine, etc., when thymol is being administered.

Small doses of thymol administered orally produce reflex stimulation of the heart and the respiratory centre; large doses produce a marked depression and finally paralysis. The central nervous system is always affected to a certain extent. There is at first a slight stimulation of the cerebral cortex followed by depression which gives rise to narcotic effects. Headache, buzzing in the ears, dizziness, lowering of the body temperature and collapse follow when large quantities are absorbed.

Given by the mouth in doses of 15 to 30 grains (1 to 2 gm.) most of the thymol is absorbed for none is found in the faeces. About half of the drug ingested is excreted in the urine partly in combination with sulphuric and glycuronic acids, partly unchanged and partly oxidised to a bivalent phenol-thymol hydroquinone. The greenish tint so often noticed in the urine after administration of thymol is due to the presence of this substance. The kidneys are irritated after large doses and albuminuria may result. When given in excessive doses it is also excreted in the bronchial mucous membrane and may produce inflammation of the lungs. The drug has no direct effect on the uterine movements but it may reflexly stimulate them by irritating the pelvic viscera.

In vitro thymol has a powerful action on earthworms. In 1 in 2,000 solutions the worms show signs of irritation and their movements are markedly increased at first, but they are soon paralysed and die in 10 to 15 minutes. In 1 in 10,000 solution they are killed in $1\frac{1}{2}$ hours; and

1 in 20,000 they are rapidly paralysed but are not killed. Hookworms are killed by weak solutions of the drug.

Anthelmintic effects. There is no unanimity of opinion about the effective dose of thymol. Some authors have recommended as much as 120 to 150 grains in divided doses of 25 to 30 grains, while others consider such large doses are neither necessary nor justifiable. They do not advise more than 60 grains of thymol in a day and recommend not to repeat it in less than a week. In pregnant women the dose should not exceed 30 grains, and in cases of extreme debility from old age, heart disease, chronic diarrhoea and dysentery the dose should be small and divided. The drug should at once be stopped if untoward symptoms appear. Ashford and King recommend the following scale of dosage:—

Under 5 years 8 grains (0.5 gm.) ; 5—10 years 15 grains (1.0 gm.) ; 10—15 years 30 grains (2.0 gm.) ; 15—20 years 45 grains (3.0 gm.) ; 20—60 years 60 grains (4.0 gm.) ; over 60 years 30—45 grains (2 to 3 gm.).

It is customary to give the drug in two or three divided doses, of 15, 20 or 30 grains each at intervals of 1 to 2 hours followed by a strong saline purgative. It is better not to give coarse crystals as these are likely to pass through the bowels unchanged, probably without coming in contact with the parasites. The drug also has a tendency to pack together in hard lumps if given in capsules and it is preferable to give it mixed with sugar of milk or bicarbonate of soda. In case of children who are not capable of swallowing capsules, thymol is best given in powdered form suspended in simple syrup or mixed with chocolate.

The preparation of the patient is important when thymol is being given as an anthelmintic. The following procedure is recommended (Ashford).

The patient is given a light meal and one ounce of saturated solution of magnesium or sodium sulphate the night before. At 8-30 a.m. the following morning 30 grains (2.0 gm.) of powdered thymol are given in capsules; at 10 a.m. another similar dose is given; at 11 or 12 o'clock, 1 ounce of saturated solution of magnesium sulphate is given. No break-

fast is allowed and food is only permitted after the bowels have moved. The patient should remain in bed and should use a bed pan.

Thymol is the classical drug for the treatment of hookworm infections, but more than one course of treatment is often required to produce a cure. In Ashford's series 68.6 per cent. were cured in 30 days and 94.4 per cent. in three months (presumably 4 to 8 treatments). He is of opinion that the drug is more effective against mature worms. Fourteen to fifteen days after infection the worms develop a buccal capsule and attach themselves to and feed on the mucous membrane. From this time onward they are exposed to the action of the drug and treatment should then be given. Darling, Barber and Hacker succeeded in removing 95.7 per cent. of necators and 57.9 per cent of ankylostomes with a single dose of 60 grains (4.0 gm.) of thymol. Even with such large doses as 180 grains (12.0 gm.) the drug is less effective against ankylostomes than other available anthelmintic. Clayton Lane (1928) still regards it as the best anthelmintic against hookworm, since even after 60 grain doses no death occurred in his series.

The effect of thymol on other intestinal nematodes is distinctly inferior to its effect on hookworms. *Ascaris*, *trichuris* and *oxyuris* are not very vulnerable to its action. Tapeworm segments are expelled but the removal of the heads is very doubtful. Thymol has also been used in trichiniasis and the parasites are expelled when they are present in the gut. Good results have also been obtained even when the parasites have lodged in the muscles. A 6 per cent. solution of the drug in oil has been given intramuscularly in doses of 2 to 3 c.cm., injections being given daily. No toxic symptoms are observed and there is marked improvement in the patient's condition. Trichiniasis can be prevented if treatment *per os* is begun within 24 hours of the ingestion of infested meat, with 2 grains (0.13 gm.) of thymol repeated three or four times and followed by a purge.

Other uses. Thymol in concentrations of 1 grain in an ounce is used for spraying the nasal mucous membrane in catarrhal affections. For general disinfection a solution of 1 in 200 (one tablespoonful in 5

pints) should be used; thymol has also been used as a paint in ring-worm, eczema and various skin diseases. In amoebic dysentery considerable benefit is obtained by colonic irrigation with 1 in 2,000 solutions in conjunction with emetine bismuth iodide. In flagellate diarrhoea, an enema with 1 in 2,000 solution and 4 to 8 grains (0.25 to 0.5 gm.) of thymol by the mouth are recommended. A 5 per cent. solution in alcohol and 2.0 per cent. in cinnamon oil is used as a paint to control infestations of the skin by fungi. One to 2 grains (0.06 to 0.13 gm.) are given 3 or 4 times a day in typhoid fever with tympanitis.

Toxic effects. In large doses thymol produces symptoms resembling carbolic acid poisoning. There is usually acute pain over the epigastrium, due to the caustic and irritant action of the drug on the mucous membrane of the stomach; nausea and vomiting follow and the patient becomes prostrated. Giddiness, roaring sounds in the ears, drowsiness, etc., commonly occur; there is often salivation and cyanosis, and the patient may become unconscious. The temperature has a tendency to fall below normal and both the pulse and respiration are slowed; skin rashes may appear; the urine may become scanty; abortion may follow in pregnant women. With very large doses collapse may be rapidly produced and death may occur in a few hours. The intensity of symptoms depends on the amount absorbed, and the presence of solvents like fats and alcohol strongly increases the tendency to produce intoxication. A purgative given a few hours after the drug prevents intoxication by washing it out of the gut. Sometimes the intoxication is delayed and sets in several days later when all the symptoms except weakness have disappeared.

Treatment of poisoning. The stomach should be rapidly washed out with warm water. Demulcents may be given to prevent corrosion of the mucosa. Cardiac and respiratory stimulants, *e.g.*, 1/120 grain (0.005 gm.) of atropine and 1/30 grain (0.002 gm.) of strychnine should be given. Hot coffee is useful in overcoming weakness. Alcoholic stimulants and tinctures are contraindicated.

Precautions and contra-indications. Thymol should be given with caution when there is anæmia, nephritis, advanced cardiac disease, pregnancy and debility due to old age. Patients suffering from chronic diarrhoea and dysentery also take it badly.

Thymotal. Attempts have been made to lower the toxicity of alkyl phenols by converting them into non-irritant esters, such as carbonates, carbamates, etc. Thymotal or thymol-carbonate is prepared by passing phosgene gas through a concentrated solution of thymol in an aqueous solution of caustic soda. It was at one time considered to be a very effective remedy against ankylostomes, but later it was found to be absolutely useless even in 40 grain doses. Although these esters are broken up in the alimentary tract by hydrolysis forming the original hydroxyl compounds, they do not attain sufficient concentration to be effective anthelmintics.

Isothymol or carvacrol was synthetically prepared from turpentine during the Great War when the supply of thymol from Germany was stopped. Chemically carvacrol is an isomer of thymol and its pharmacological action bears a close resemblance to thymol in many respects. The anthelmintic action of carvacrol was tested by Sollmann on earthworms with fairly satisfactory results. The International Health Board reported unfavourably on its efficiency against hookworm. Caius and Mhaskar (1924) tried carvacrol in 20–60 minims. doses with promising results. They found it to be a good anthelmintic but decidedly inferior to thymol. It is also more irritant and somewhat more toxic than thymol.

Preparations.

Thymol disinfectant (Martindale). It is a potent antiseptic; when employed as a general disinfectant, 1 in 200 solution in water should be used.

Liquor thymol is made of 1 part of thymol in 800 parts of warm water; used as an antiseptic gargle well-diluted.

Mistura oleobalsamica. Dose is 1 to 4 drachms in water as a carminative stimulant.

Pastilli thymol. Contains 1/32 grain of thymol in each.

Pigmentum thymol. It consists of thymol 1 part, ether 10 parts and spirit 5 parts or may also be prepared with petroleum oil; useful in ringworm of the scalp.

Thymaglycine. It is a palatable preparation containing sodium benzoate, menthol, essential oils, glycerine and thymol water. It is given in rhinitis, pharyngitis, quinsy, etc., or as a spray for throat and nostrils, diluted 1 to 3 in water. For colitis in children 5 to 10 min. in paraffin or water are given.

Glycethymellae. It consists of potassium carbonate, sodium benzoate, sodium borate, sodium salicylate, thymol, menthol, glycerine and alcohol coloured with cochineal. It is frequently prescribed as an intestinal antiseptic in doses of $\frac{1}{2}$ to 1 drachm and also as a gargle.

Unguentum thymol. Prepared in strength of 20 grains (1.3 gm.) in an ounce of soft paraffin useful in eczema. A compound ointment has boric acid and zinc oleate in addition.

Thymol carbonate (Thymotal). It is a colourless and tasteless crystalline powder employed in ankylostomiasis in doses of 5 to 15 grains (0.3 to 1.0 gm.).

Thymoform is obtainable in the form of lozenges containing thymol and formic aldehyde in a cane-sugar basis.

BETA-NAPHTHOL

Beta-naphthol has been used as an anthelmintic for quite a long time. As early as 1904, Bentley used the drug against hookworm in Assam and later in 1908, Burkitt and Drummond tried it with excellent results. The chief merits claimed on its behalf are that it is not unpleasant to take, it is more satisfactory for routine use and is one-tenth the price of thymol. Caius and Mhaskar reported very favourably on the drug and recommended it as the safest and most efficacious anthelmintic for hookworms, but subsequent work has failed to substantiate their claims. With the advent of carbon tetrachloride and oil of chenopodium beta-naphthol is gradually receding from the field though it is still used in some places.

Source and composition. Naphthol is derived from the hydrocarbon naphthalene by the substitution of a hydroxyl for one of the hydrogen atoms. There are two naphthols—the alpha- and the beta-naphthols—the former is very toxic and is not used in medicine.

Beta-naphthol occurs in colourless glistening crystals of pale buff-coloured lamellæ. It has a faint phenol-like odour and has a pungent hot taste; it is very slightly soluble in cold water but dissolves readily in boiling water. The drug is of uniform quality and does not readily change or deteriorate though it is better kept in amber-coloured bottles.

Pharmacological action. Externally beta-naphthol is irritant to the unbroken skin and may be absorbed therefrom producing toxic symptoms. It produces inflammation and corrosion of mucous membranes and raw surfaces. Beta-naphthol can be taken by healthy individuals in fairly large quantities without producing any untoward symptoms. As a rule, a slight degree of warmth is felt in the stomach, but there is no burning pain, nausea and vomiting as in the case of thymol. Beta-naphthol is sparingly soluble in saliva and in the gastric juice, hence its absorption from the stomach is slight; it is more readily absorbed from the small intestine. The peristaltic movements of the intestine are increased and some purging results. Large doses produce an irritant action on the gut and produce nausea and vomiting.

The heart is reflexly accelerated at first, but later it becomes slower which is due to direct action on the cardiac muscle. In large doses, it

has a toxic effect on the red blood corpuscles, especially in patients with active or latent malaria. The corpuscles may be destroyed in sufficient quantities to produce hæmoglobinuria, jaundice, and severe anaemia.* Large doses depress the respiration probably from depression of the respiratory centre. Therapeutic doses have no effect on the central nervous system, but after absorption of large amounts, it produces giddiness and convulsions followed by paralysis and coma. Changes in the retina and opacity in the lens have been produced in some cases, after its use.

Beta-naphthol is rapidly excreted in the urine and during its excretion it may produce inflammation of the kidneys, even when the doses taken are not large. It is excreted in combination with glycuronic and sulphuric acids and imparts to the urine a dark brown or mahogany red colour. Although salivation is produced, it is not excreted in the saliva.

Anthelmintic effect. There is great diversity of opinion about the toxicity and efficacy of beta-naphthol as an anthelmintic. The dosage recommended varies from 30 to 90 grains (2.0 to 6.0 gm.), on three successive days until the total quantity has been given. Such large doses often produce destruction of the red blood corpuscles; doses of 30 grains (2.0 gm.), on the other hand appear to be too small. According to Caius and Mhaskar, the drug is quite safe and effective in doses of 50 grains (3.3 gm.) in a single dose, and 60 grains (4.0 gm.) divided into two doses. There is again no definite rule about the use of the pre-purge. The omission of the preliminary purge is not attended by any fall in anthelmintic efficiency and the after-purgative is often unnecessary in as much as the drug itself has got a purgative effect. It is, however, better to use both the pre- and post-purgative, for this procedure decreases the chances of production of untoward effects.

Beta-naphthol has been found by nearly all workers with the exception of Caius and Mhaskar to be less efficient than thymol, and certainly less so than oil of chenopodium or carbon tetrachloride. Usually at least four or five treatments are necessary before a cure is effected. Its action on ascaris and trichuris is no more promising than its action in hookworms. Smillie in Brazil removed only 52 of 124 ascaris (41 per cent.) as compared with 91 per cent of 454 cases removed by chenopodium. *Tenias* are also very little affected by it.

Toxic effects. The toxicity of naphthalene bodies in man varies widely. Naphthalene has been taken in 75 grain (5.0 gm.) doses without ill effects, while much smaller quantities have produced severe gastroenteritis. Deaths have been reported from the external use of a mixture of 1 part of beta-naphthol and 2 parts of camphor. In man, restlessness followed by convulsions and coma with stertorous breathing, have been seen even in non-fatal cases. Naphthalene and beta-naphthol are toxic drugs, 2 drachms (8 gm.) causing death in a rabbit; in the dog the fatal dose is 1.0 gm. per kilo.; cats die of convulsions after 1.5 grains (0.1 gm.). Large doses produce a burning sensation in the epigastrium, diffuse abdominal pain, nausea, vomiting, diarrhoea, or even dysentery-like symptoms, spasm of the face muscles, weakness and fever. Micturition is painful, the urine becomes very dark, scanty, and shows the presence of bile, albumen and casts; suppression of urine may supervene, producing uræmia. The spleen, the liver and the kidneys are enlarged and hyperæmic, and the gall bladder is distended. Death may occur from convulsions or gradual failure of respiration, the heart goes on beating after the respiration has stopped. All these symptoms are more readily produced in malarial patients. The Porto Rican Anæmia Commission tried the drug extensively and found that 83.3 per cent. of their cases who took it suffered from albuminuria. Cairns and Mbaskar (1921) noted that all their cases of albuminuria and hæmoglobinuria occurred with doses over 60 grains administered for several days. With small doses no such symptoms were produced.

Precautions and contra-indications. The urine of patients should be always examined before administering the drug, and if the kidneys are damaged it should be given with caution. Large doses should not be given to those who are suffering from or have suffered from malaria.

Preparations.

Naphthol (B.P.) and beta-naphthol (U.S.P.X.). Dose 15 to 30 grains (1 to 2 gm.), but 40 to 50 grains in single or divided doses is considered quite safe. It is usually given in the form of cachets or pills or in the form of an emulsion in oil. **Betol or beta-naphthol salicylate (N.O.)** has no anthelmintic action. Dose 4—8 gr., used in the form of cachets or pills or as emulsion in milk in rheumatism, cystitis and intestinal catarrh. **Benzonaphthol or beta-naphthol benzoate (N.O.)** has also no vermifugal action, used as diuretic and intestinal antiseptic. Dose 15 grains (1.0 gm.). **Beta-naphthol petroxalin (N.F.)** 10.0 gm. of beta-naphthol dissolved in 90 gm. of liquid petroxalin used as a parasiticide application. **Naphthalenus (N.O.)** has been tried against hookworm but has no anthelmintic action. Dose the same as beta-naphthol. **Naphthalene tetrachloride** was tried in 8 grain (0.5 gm.) cachets every 4 hours in colitis.

RESORCINOL DERIVATIVES

A number of synthetic compounds have been prepared and some, the isohexyl derivatives of either resorcinol or phloroglucin, are promising.

HEXYLRESORCINOL

Hexylresorcinol is 1 : 3 dihydroxy - 4 - hexylbenzol. It is a white, waxy, crystalline substance and is quite stable. It is sparingly soluble in water (1 in 1,700) but it readily dissolves in alcohol, ether, chloroform and vegetable oils. Hexylresorcinol is considered to have highly germicidal properties, the phenol co-efficient varying between 46 and 52. It has been used as a mouth wash, gargle, nose and throat spray in concentration of 1 in 4,000. It has been administered in gelatine capsules in doses of 0.45 to 0.6 gm. three times a day, as an urinary antiseptic. The drug has been continued for as long as ten weeks without showing any deleterious effects. For children, a 2½ per cent. solution of the drug in olive oil under the name of Caprokol (N.N.R.) has been prescribed two or three times a day. It has been highly spoken of in cystitis and pyelitis and appears to be well tolerated.

Pharmacological action. Crystalline hexylresorcinol has irritant properties and is liable to produce a burning sensation in the mouth. The irritating property of the drug can be overcome by dissolving it in olive oil but this reduces its vermifugal power. A solution of 0.1 per cent. of hexylresorcinol *in vitro* killed pig ascaris in 2 minutes while it took more than 20 minutes to be effective in 3 per cent. olive oil solution. Repeated administration to dogs is known to have produced petechial hemorrhages in the buccal and gastric mucous membranes. The drug is, however, precipitated by proteins, and probably on this account it does not penetrate deeply into the tissues. When given with alcohol absorption is facilitated. Experiments on dogs show that about 27 per cent. of hexylresorcinol taken by the mouth is excreted in the urine and 67 per cent. is eliminated in the feces.

Anthelmintic properties. The anthelmintic property of the drug has been noticed only recently. Lamson and others in America were the first to study the effect of hexylresorcinol as an anthelmintic. They found that the drug in large dilutions was lethal to pig ascaris *in vitro*. It removed 100 per cent. of the ascaris in 16 out of 17 dogs as shown by autopsy, and it removed 90 to 100 per cent. of these parasites in 20 patients when given in 1 gm. doses in gelatin capsules. This was

followed later by more systematic investigation by Lamson, Caldwell, Brown and Ward (1931) into the effectiveness of the drug in human ascariasis. They administered the drug in hard gelatin capsules to avoid the local irritant effect, the maximum dose being 1.0 gm. for adults, magnesium sulphate being given two hours after. They succeeded in curing 7 out of 10 cases; the egg reduction amounted to 96.4 per cent. in a total of 5 cases, all of whom were cured. The reduction was cent. per cent. if the purgative was deferred for 24 hours. Food, shortly before or after the treatment, greatly reduces its efficacy. Similar results were obtained by Lamson and his co-workers in field work in ascaris infection. They also tried the drug in hookworm infestation of children and egg-reduction was 80—80 per cent. with a single dose. Lamson and his co-workers (1932) in evaluating the comparative results of hexyl and heptylresorcinol considered the former to be a better anthelmintic. In hookworm infection, in a total of 25 cases given doses of 1 gm., the average egg-reduction was 62.7 per cent. but none was cured. In ascariasis, in doses varying from 0.8 to 1.0 gm., the cure rate was 29.4 per cent. and the average percentage of egg reduction was 73.5. Lamson, Brown and Ward (1932) consider a single dose of hexylresorcinol to be capable of removing more than 90—95 per cent. of ascaris, 80—85 per cent. of hookworms and 40—45 per cent. of trichuris. Brown (1932) calls attention to the possibility of reaction taking place between gelatin and hexylresorcinol when given in capsules, especially in hot moist climate. He advocates sugar-coated pills in dosage of 0.1 gm. per year of age up to 10 years and 1.0 gm. to every one above this age. The treatment was started in the morning the drug being given in an empty stomach, and food was withheld for 4 to 5 hours afterwards. The average egg-reduction was 90 per cent. of ascaris and 32 per cent. of trichuris. Two doses of hexylresorcinol with an interval of 3 weeks between the courses, reduced the ascaris egg count to 96 per cent. and the rate of cure was about 93 per cent. Maplestone and Mukherjee (1932) using the drug in hard gelatin capsules, under strict fasting conditions, obtained a cure rate of 66.6 per cent. and an egg-reduction of 94 per cent. in 21 cases. In hookworm infestation in 26 cases the corresponding figures were 7.7 and 71.4. In ten cases of teniasis no head was recovered after giving the drug but five reported no recurrence 3 months later. Biggam and Ghalioungui (1932) treated 50 cases of *ankylostoma duodenale* and only 26 patients were found to be free from the parasites even when repeated administration of as much as 2 gm. were employed. The drug did not produce any toxic symptoms, but the results were far less encouraging than with other available anthelmintics.

Method of administration and dosage. Before administering the drug, proper dietary preparation is necessary. In the evening previous to the commencement of the treatment, only

milk and bread should be given. Early next morning hexylresorcinol is given in hard gelatin capsule in doses of 1.0 gm. with about 2 ounces of water to help in swallowing the drug. No food is allowed for 4 to 5 hours and alcohol is forbidden. Reaction between the drug and gelatin can be avoided if the capsules are filled immediately before they are administered. Sugar-coated pills each containing 0.2 gm. are available and they are unaffected by climatic conditions. They are quite convenient to use except that in children they may cause a superficial burn in the mouth if they are chewed, on account of the protein-precipitating property of the drug when it comes in contact with the mucous membrane. In the majority of cases, hexylresorcinol exerts a cathartic action and the patient has five or six watery stools after it. A dose of magnesium sulphate should however be given next morning, *i e.*, 24 hours after the dose. The toxic symptoms observed are negligible. Some of the patients may complain of pain in the epigastrium but this is very rare, even with doses as high as 2 gm. for a single administration. Repetition of the dose even at short intervals in maximum quantity does not produce any toxic symptoms. Hexylresorcinol, so far as is known has proved of value in ascariasis; in ankylostomiasis and other helminthic infection its superior efficacy over other drugs has yet to be worked out. Probably in hookworm infection, in anæmic and debilitated subjects it may be a safer drug than the other remedies in use.

HEPTYLRESORCINOL

On account of the results of hexylresorcinol in the treatment of helminthic infestations other alkyl resorcinols have also been used. Heptylresorcinol is one of them. Locally, it produces a smarting burning effect on the tongue and is irritant to the buccal and gastric mucous membrane. About 80 per cent. of heptylresorcinol is excreted in the faeces. Lamson and his co-workers (1932) in a comparative study of the effect of the two resorcinols in helminthic infections found that hexylresorcinol seemed more effective against hookworm, ascaris and trichiuris than heptylresorcinol. The average egg-reduction in hookworm disease with 1.0 gm. doses of heptylresorcinol was 55.2 per cent., in ascaris 78.5 per cent. and in trichiuris 35.8 per cent. Mackie (1931) using sugar-coated pills containing 0.15 gm. found that none of the intestinal protozoa were affected by the drug with the exception of *Iodamoeba butschlii* and

Giardia intestinalis. Thonnard-Neuman (1931) reports that cases of hookworm infestations proved refractory towards heptylresorcinol dissolved in olive oil. David and Johnstone (1933) treated 23 cases of hookworm infection with the drug; six were treated with olive oil solutions of heptylresorcinol, but this proved ineffective. The crystalline drug in gelatin capsules was later tried, which proved partially successful; trichiuris infection proved refractory.

Heptylresorcinol is generally given in hard gelatin capsules in doses of 1.0 to 1.5 gm. preferably in the morning on an empty stomach and food is withheld for 4 to 5 hours. Solution of the drug in olive oil greatly lowers its efficacy. A purgative should be prescribed several hours later. The drug has also been prescribed in gelatin capsules coated with salol. This prevents liberation of the drug in the stomach so that it may reach the parasites in the intestine in an effective concentration. The results of treatment are more favourable in hookworm infection than in ascariasis or tapeworm infestations.

Preparations.

Hexylresorcino'ls (tablets 0.2 gm.), **Liquor Hexylresorcinolls** (1 in 1,000).

CHAPTER VII

MISCELLANEOUS ANTHELMINTICS

Intestinal antiseptics. Some of the compounds which show well-marked disinfectant properties in the gastro-intestinal tract, such as thymol and beta-naphthol, have proved excellent anthelmintics. This observation opened up the possibility of other intestinal antiseptics behaving in a similar manner. With this idea in view, a number of reputed intestinal antiseptic drugs have been tried to determine their vermifugal properties. It has been found, after a large series of experiments conducted by workers in different parts of the world, that these drugs, with the possible exception of some of the propenyl derivatives of phenol and salicylic acid esters, are useless as far as their anthelmintic activity is concerned. Some of these are positively dangerous to the host instead of being in any way inimical to the parasites.

Potassium permanganate in maximum doses, bismuth carbonate, kaolin, naphthalene, phenocoll, methylene blue, guaiacol carbonate, creosote, izal, salicylic acid, salol, acetyl-salicylic acid (aspirin), salicylic ester of beta-naphthol (betol), the crude phenols, etc., have all been tried and found to be useless.

Methyl salicylate, a volatile ester of salicylic acid has, however, well-marked vermifugal properties. In doses of 30 to 60 min. (2 to 4 c.cm.) it has been found to be very effective against hookworms, but has little or no effect on ascaris and trichuris. Methyl salicylate is present in oil of wintergreen (*oleum gaultheria*) in large quantities (99 per cent.). It has been given in 30-60 min. doses with castor oil and gum acacia with satisfactory results.

A number of propenyl phenols occur in nature, *e.g.*, anethol, eugenol, etc. These are fairly good anthelmintics and do not possess the toxic properties on the host, of the crude phenols.

Purgatives. These drugs have got very little vermifugal action but they irritate the gastro-intestinal tract and in this way bring about a vermifugal effect. Magnesium sulphate, calomel, phenolphthalin, *oleum ricini*, *oleum tiglii* and aloe have all been tried at some time or other by different workers, but they have no vermifugal properties. Whipworms (*trichuris*) have been successfully treated with two ounces of castor oil on four successive days, followed by an enema of 2 litres of 0.5 per cent. solution of sodium carbonate with one ounce of kaolin added to it. The patient is kept on a low diet and is also given one ounce of kaolin daily on each of these days. After four days of treatment the enema is continued for two days more.

Heavy metals. A number of other drugs have been used for their anthelmintic effects in man and animals. Copper sulphate has chiefly been used in veterinary practice, especially in infection with *Hæmonchus contortus*, the stomach worm of sheep. The arsenical compounds such as stovarsol have been given but their vermifugal effect is doubtful. Injections of organic arsenicals and tartar emetic have been found to have some effect on *clonorchis* infections in man. Salvarsan and sulpharsenol injections have been given in oxyuris and guineaworm infections with success in some cases. Mercurochrome has been given intravenously against *Schistosoma japonicum* in man in 1.0 per cent. solution, with some degree of success.

Embellia ribes and **E. robusta** family Myrsinaceæ, had the reputation of vermicidal action, but Caius and Mhaskar (1923) showed them to be quite ineffective against hookworms, round worms and whipworms. The chief constituent of the fruit is embelic acid, which occurs in golden-yellow crystals, resin and tannin. Anthelmintic dose 1 to 4 drachms (4 to 10 gm.) of the powdered drug.

Azadirach. The bark and root of *Melia azadirachta* has been used as an anthelmintic against roundworms. The active constituent of the drug is margosic acid and a resin. In India and in the southern United States, the fresh bark of the root is employed to expel ascaris. The powdered bark is given in doses of 20 grains (1.3 gm.), or the decoction (made by boiling 2 ounces of the bark in a pint of water until reduced to half) is given in one tablespoonful doses hourly or every second or third hour; a purgative is given after the second or third dose. The oil has no anthelmintic properties. In excessive quantities the drug produces dizziness, purging and collopse.

Corsican moss (helminthochortan) is a mixture of various marine algæ and is used in France and Italy to expel ascaris. It is best given as a sweetened decoction with milk in a single dose before breakfast. Dose for a child under two years is 15 to 45 grains (1 to 3 gm.); of 10 years 3 to 4 drachms (12 to 15 gm.). It is sometimes combined with santonin or santonica.

Mucuna or Cowhage is the fruit of *Mucuna pruriens* a climbing plant of tropical America. The pod is covered with stiff hairs which produce intense itching. Cowhage acts mechanically, the hair piercing the parasites. The pod is dipped in molasses and the hairs are removed by scraping. Dose is one teaspoonful for a child and one tablespoonful for an adult. The drug has been used both against roundworms and tapeworms, but it is too disagreeable to take and too uncertain in its action.

Butea frondosa has been used as an anthelmintic against roundworms but opinions differ regarding its efficacy. The seeds have been analysed and they contain 16 per cent. of a fixed oil called *moodooga oil*, small quantities of resin and large quantities of a water-

soluble albuminoid. There are no active principles of the nature of alkaloids, neutral principles or glucosides. The powdered seeds have been used as an anthelmintic in doses of 30 to 60 grains (2.0 to 4.0 gm.), but they are unpleasant to take and often produce pain in the stomach, vomiting and giddiness. The oil and the resin were separately tested against hookworm and ascaris. The alcoholic extract, the oil and resin had no effect, but freshly powdered seeds produced good results in ascaris infection. Old worm-eaten seeds met with on the market are inactive.

Ficus laurifolia has been recommended as an anthelmintic against whipworm in man in doses of 15 to 30 gm. The latex of this plant has definite anthelmintic properties and is worthy of trial. The active principle is unknown though it probably resides in the solid portion of the latex. In its natural state, the latex forms a perfect emulsion of rubber and resinous substances; it contains an albumin and substance of fixed composition yielding ammonia, which is probably responsible for its anthelmintic activity. The latex unfortunately readily ferments and will only keep for 4 to 5 days, though in an ice box it has been kept for several months. The drug is very effective against whipworms (*Trichuris trichiura*). It may produce toxic symptoms, colic, nausea, vomiting, muscular cramps, delirium, syncope, urticaria, rectal and vesical spasms, and partial suppression of urine.

Quassia is the wood of the trunk and branches of *Picraena* or *picrasma excelsa*. *Picrasma quassioides* Benn is a common shrub growing in the sub-tropical Himalayas. The active principles of quassia are substances called picrasmin and quassin.

Quassia is poisonous to many insects and is used as an insecticide. It has been used as an anthelmintic against threadworms for a long time. Kennard (1915) tried quassia in ankylostomiasis without success but Barnes (1915) claims to have cured 70 per cent. of cases with the drug. Caius and Mhaskar by giving 5 ounces of an infusion of the drug prepared by adding 1 ounce of finely powdered root to a pint of boiling water, failed to cure any case. It has, however, been found effective in threadworms especially in children; generally the decoction is given in the form of an enema, but quassia suppositories containing $\frac{1}{2}$ grain (0.016 gm.) of the extract with a gelatin basis, may also be prescribed. Two grains of the extract of quassia in the form of a pill taken three times daily along with some purgative are also given to clear out threadworms.

Spigella marilandica or pinkroot is a plant belonging to the family Loganiaceae which is widely spread all over the southern parts of the United States. It was formerly considered as a powerful anthelmintic especially against ascaria.

The constituents of the root are *Spigelline*, which is a volatile alkaloid resembling nicotine and conine, a bitter principle soluble in water, a volatile oil and resin.

Very little is known about the action of this drug. The alkaloid is a gastro-intestinal irritant, and in poisonous doses it produces convulsions. It is absorbed slowly from the 'gut and if combined with a purgative it does not produce any toxic effects. Sollmann (1918) tested its activity on earthworms but his results were not promising. Pink-root is chiefly used as a vernifuge against roundworms and is said to be quite effective against them. Careful experiments on animals have shown that it has no marked anthelmintic action against any of the parasites.

Chrysanthemum cinerariæ. The active principle is said to be a good parasiticide, it is non-toxic and non-irritant. It is said to be useful in ascariis, trichuris, threadworm and tapeworm infections.

Rhumnus cathartica. A syrup made from the berries with jalap is said to be useful in oxyuriasis.

Allium sativum. The allyl compounds contained, produce complete paralysis of ascariis *in vitro*, but their anthelmintic effects in man are doubtful.

Geraniol in doses 0.3 c.cm. per kilo. body weight has been tried in dog but has no effect. Various species of *Cambrethum* occurring in Brazil, extracts of *C. quadrangulans*, essential oils of *Tageterminulus* and *Kyllinga odorata* were quite ineffective.

Acalypha indica, petroselinum sativum and **quisqualis indica** have no anthelmintic properties.

Rotylon. It is an aromatic combination, insoluble in water, but soluble in alkalies, manufactured by Bayer Meister Lucius Ltd. The drug is set up in capsules each containing 0.4 gm. When taken in liquid form it produces a burning sensation in the tongue which is followed by one of prolonged anæsthesia. The anthelmintic properties of this drug are under investigation.

Vernonia anthelmintica. Powdered seeds in doses of 30 to 60 grains have a weak vermifugal action against ascariis and a more powerful action against oxyuris. The bitter substance isolated, in doses of 3 to 10 grains, has a weak vermifugal action against ascariis and a decided action against oxyuris. When combined with calomel and followed by magnesium sulphate the vermifugal action is considerably enhanced. The drug has no action whatsoever against the hookworm and tapeworms. The anthelmintic properties of the drug against ascariis and even against oxyuris are weaker and in no way comparable with some of the other compounds now in the British Pharmacopœia.

CHAPTER VIII

ANTHELMINTICS ACTING ON SOMATIC PARASITES

Although this subject is of very great importance very little is known about it. The absorption of the drug is essential for any action to be produced on blood and somatic worms, and since most of the anthelmintic remedies are toxic to the host when absorbed in more than very small quantities, the difficulty of finding a suitable drug to destroy the parasites is great. Helminthic parasites may occur almost in every organ and tissue in the body, and some are more easily reached than others. The parasites lying in the liver are easy to reach since the drugs absorbed from the gut go through this organ first, and they reach it in high concentration. The parasites lying in the lungs can be reached by drugs given by inhalation, and parasites in the blood can be reached by drugs from the digestive tract or by injection. Parasites lying in the subcutaneous tissue, muscle, central nervous system, etc., must be reached indirectly by drugs circulating in the blood stream, which are therefore much diluted by the time they reach the parasites.

The principal human somatic or extra-intestinal parasites important from point of view of anthelmintic treatment are, (1) flukes, parasitic in the liver, bile ducts, or pancreatic ducts; (2) lung flukes; (3) schistosomes located in the mesenteric blood vessels; (4) tapeworm cysts in muscles, liver and other viscera and the central nervous system; (5) filariae situated in lymph glands or ducts. The embryos of trichina worms during their wanderings in the blood stream and muscle tissue, before encystment in the muscle fibres may also be considered capable of anthelmintic treatment.

The drugs which are considered effective against these parasites are practically the same as those used against intestinal helminthic infections. During recent years a few more drugs have been added to the list, *e.g.*, antimony compounds, emetine, carbon tetrachloride, etc. The anthelmintic properties

of these drugs will be considered separately. The anthelmintic treatment of somatic infections can best be considered from standpoint of the groups of parasites.

Trematode infections. *Clonorchis sinensis* or liver fluke is an important hepatic fluke of man; *Fasciola hepatica* and *Dicrocoelium lanceatum* rarely infect mankind.

Clonorchis sinensis or *distoma sinensis* lives in large numbers (several thousands) in the bile ducts and dilated biliary canals in the liver. It is widely prevalent in Eastern Asia and Indo-China. Injections of arsenicals and tartar emetic have been successful in some cases.

Oil of chenopodium is said to have some effect on clonorchis in man and animals. Emetics have been recommended, as vomiting dislodges the parasites and expels them. Tartar emetic combined with intensive courses of sulpharsenol has been recommended, the injections of the two drugs being given alternately. Mercurochrome by the mouth as well as intravenously proved ineffective. Injection of methyl violet, crystal violet and Nile blue sulphate have been tried against *Clonorchis sinensis*, but these drugs have been found ineffective. Gentian violet in doses of 15 to 20 mgm. per kilo. can be tolerated by the mouth. Intravenous injections of a 1.0 per cent. solution are said to be very effective against clonorchis; 20 c.cm. are given for the first dose followed by 30 c.cm. three days after. No untoward symptoms are observed and eggs disappear from the faeces.

Fasciola hepatica or *distomum hepaticum* is much rarer in man but common in sheep. Injections of antimony have been advised; carbon tetrachloride is useful.

Paragonimus westermani or *ringeri* occurs in Japan, Korea and China. The cercarial stage develops in snails of the genus *Melania*. It especially affects the lungs of man, producing hæmoptysis. Emetine injections are useful.

Fasciolopsis buski infects pigs and is occasionally found in man in the East Indies, Bengal, Assam and China. Thymol is mainly relied on and carbon tetrachloride is said to be more efficacious; 75 grains (5.0 gm.) of beta-naphthol in adults

divided into three doses given hourly are said to be more satisfactory.

Gastrodiscus (Amphislomum) hominis is met with in human intestines in India, Assam, Malay States and Indo-China. Its pathogenesis is doubtful. The first drug used for attacking flukes was aspidium or male fern as early as 1884. Drugs such as calomel, aloes, sodium salicylate, compounds of arsenic, mercury and antimony have been tried but the results have not been encouraging.

Blood flukes. Human schistosome infection is common in Egypt, South Africa, China and Japan. The adult worms live in the portal veins and its tributaries and lay ova which work their way to the venules on the surface of the bladder or rectum.

Schistosomes. Three species occur in human subjects. *S. japonicum* occurs in Eastern Asia especially China; *S. hæmatobium* affects the genito-urinary tract, and *S. mansoni* mainly involves the lower portion of large gut. The last-named is more widely prevalent in Africa, and to a less extent in south-west Asia and tropical America. The larval worms of *S. japonicum* after escaping from the snail, penetrate the skin of man. After infection of the definitive host, sex differentiation is recognisable by the 6th day, mating occurs by the 17th day, but sexual maturity is not attained until the 30th day. In the absence of males the female flukes remain immature for months until a male is introduced, when they mature rapidly. The intermediate host of *S. japonicum* is *Hemibia japonica* and *H. hupensis*; of *S. mansoni* is *Planorbis boissyi* in Egypt and *P. guadeloupensis* and *P. olivaceus*. *S. hæmatobium* also passes through another genus of snails (*Bullinus*), several species of which could be infected by the miracidium. In South Africa *Physopsis africana*, in Iraq *Bullinus contortus* are implicated. The adult worms may be numerous in the portal veins without causing trouble, except sometimes producing thrombosis. The main pathological lesions are caused by the very numerous spined ova irritating the tissues during their sojourn in them or during their passage through the wall of the bladder to escape in the urine in case of *S. hæmatobium* and through the rectal

mucosa in the case of *S. mansoni* and *S. japonicum*. The last two accumulate in the liver and produce severe intractable cirrhosis of the organ and ascites. The spleen may be very enlarged. Warty and papilomatous growth may occur in the genitals, resembling venereal warts or carcinoma. The presence of ova in all the abdominal organs, the lungs, heart, and cerebro-spinal system has been described; tubercle-like miliary bodies may occur in these organs. An antigen from the infected snail's liver has been prepared and a positive complement-fixation test is obtained in 88.8 per cent. of infected cases. Treatment with tartar emetic and emeline is successful. Internal administration of extract of filix mass was tried in this infection with beneficial results. Thymo-benzene (2 grains thymol in $2\frac{1}{2}$ drachm benzene) organic arsenicals, santonin and methylene blue have all been tried with unsatisfactory results. The treatment with tartar emetic has been discussed elsewhere.

Cestode infection—Tapeworm cysts. The important somatic tapeworm infections of man are cysticercosis or infection with the bladder-worms of *Tænia solium*; hydatid disease or infection with the cysts of *Echinococcus granulosus*; and sparganiasis or infection with *Sparganum*, the larval stage of *Diphyllbothrium* species. The anthelmintic treatment of these infections is not hopeful at present. Male fern, koussou, kamala and pomegranate bark have all been tried but are useless.

Nematode infections—Nemathelminthiasis. *Dracontiasis* or guinea-worm infection of the subcutaneous tissue has been known from very ancient times and they are probably the 'fiery serpents' mentioned by Moses. It is a tropical disease and occurs in Africa, Asia-Minor, Arabia and India. In India, it is practically limited to the western half. On the eastern half, it is comparatively rare or absent. The infection is fairly common in the following areas in India:—North-Western Frontier Province, the Punjab, Rajputana, Central India, Bombay, Madras and Mysore. In other parts of India such as Bengal, Assam, Bihar and Orissa, and the United Provinces the disease is unknown. The factors which determine the distribution in India are at present obscure.

The female worm which is much larger than the male is 30 to 120 cm. long and 0.5 to 1.7 mm. in diameter. When gravid it migrates to the extremities. A blister is formed at the site where the worm emerges. The embryos are usually discharged whenever the worm comes in contact with water. The pathology and transmission of the disease was studied in detail by Pedschenko in 1870 who showed that fresh-water cyclops act as intermediary host. When the embryos are swallowed by the cyclops they pass into the hæmocele cavity of the cyclops where they undergo metamorphosis. In about 4–5 weeks the larvæ become mature and are ready to enter the human host. When these infested cyclops are swallowed by man the cyclops are killed by the gastric juice, but the larvæ being more active emerge from the cyclops and enter the stomach wall. They mature in the retroperitoneal tissue in about a year. After fertilisation the male worm dies and the female migrates to the limbs, which are likely to come in contact with water.

During the period of incubation no signs or symptoms are present. Just before the worm emerges from the tissue anaphylactoid symptoms like urticaria, nausea, vomiting, giddiness, dyspnoea or fever appear. These are due to absorption of the toxin secreted by the worm. Normally it takes about three weeks for the worm to empty the uterine contents. During this period if the worm breaks, serious complications are caused, resulting in cellulitis and septicæmia which sometimes end fatally. When the worm is unable to reach the surface of the skin during the migration it dies and may produce an abscess or become calcified. This may give rise to painful joints, rheumatic pains in the limbs, etc., thus causing considerable physical disability.

Complement-fixation and dermal tests with the *Dirofilaria immitis* antigen have recently been carried out in guinea-worm infection which show in all cases positive reactions.

Treatment. A very ancient method of treatment still in vogue in endemic areas is to apply cold water to the worm, which causes the uterus to empty gradually. This process is repeated daily for two to three weeks when the worm is wound on a match-stick or a similar object. If the worm breaks during the process of winding, abscess formation or sloughing results. Recently, injections of antiseptics into the body of the worm have been recommended. This is done with the object of killing the worm, when it can be extracted easily. Injections of mercuric chloride 1 in 1000 have been recommended. Acton obtained good results by injecting chinisol 1 in 400. Recently, acriflavine 1 in 1000 has been reported to yield similar results. Macfie obtained good results in dracontiasis by

a dose of injecting tartar emetic intravenously; a dose of one grain was given every other day for 4 or 5 injections.

Prevention of guinea-worm infection is simple. Drinking-water should be boiled or filtered through a fine muslin.

FILARIASIS

The principal human somatic or extra-intestinal parasites, the filariae, are situated in lymph glands or ducts. Several varieties of filariae occur as human parasites and in some sub-tropical climates produce various clinical conditions. *Wuchereria bancrofti* is widespread in most tropical countries and occurs in many of the temperate climates. The carrier is *Culex fatigans* (also called *Culex quinquefasciatus*) but other species of mosquito may also carry it. *Loa loa* is found in West Africa. With the exception of surgical measures to remove the parasite from the eye or subcutaneous tissues, there is no treatment. *Microfilaria perstans* is found in the blood of people in the West and Central Africa. *Onchocerca volvulus* is prevalent on the Gold Coast and gives rise to localised tumours. *Microfilaria nuda* is thought to be the embryos of this and the carrier is probably *Simulium damnosum*, a day-biting fly. No treatment is known.

Filarial infection was known in India from early times. The infection is present chiefly along the sea coast and along the banks of big rivers with the exception of the Indus. The disease is caused by the filarial parasite which lives in the lymphatic vessels and glands and bring about obstruction to the lymph-flow. The embryos (microfilariae) circulate in the blood exhibiting a nocturnal periodicity. Several human filarial parasites are known of which *Wuchereria bancrofti* is the most important. The male worm is 30 to 40 mm. long and the female 70 to 80 mm.

The infection is transmitted by the mosquito. Both culicine and anophiline mosquitoes act as intermediary hosts but *Culex fatigans* is the most important carrier in India. The embryo undergoes metamorphosis in the thoracic muscles of the mosquito and under favourable conditions it takes 9 days to develop. Researches by Acton and Rao have clearly brought out the various factors that are responsible for the spread of the infection. The most important of these are, (1) optimum conditions of humidity (above 60 per cent.) and temperature (80° to 90°F.); (2) density of human population, and (3) prevalence of the carrier—*Culex fatigans*. A correlation or absence of any of these factors explains the variation in the amount of infection prevalent in different

areas. It is generally found that the infection is heaviest in towns and big villages and comparatively less in the cities, the small villages being practically free.

The clinical manifestations due to *Wuchereria bancrofti* are lymphangitis, abscess, elephantiasis of extremities, genitals and breasts, lymph varix and chyluria. Anaphylactic symptoms such as urticaria, periodical headache, and small rises in temperature, are commonly observed in infected persons. These lesions are primarily caused by the toxin of the parasite. The disease is aggravated by secondary infection. In the early stages of the infection the embryos are present in the blood but as obstruction to the lymph flow increases the embryos cease to be present in the blood. In advanced stages, the adult parasite is usually dead and becomes absorbed or calcified. In cases of chyluria, however, the lymphatics are blocked, and the blood examination reveals microfilaria. When the worm is dead, as happens in advanced cases of chyluria, no microfilaria are to be seen in the blood or urine.

A survey of the filarial disease in this country reveals certain striking features of distribution. In hyperendemic areas such as in Cochin with a microfilaria rate of above 20 per cent., the prevalent type of filarial disease is elephantiasis; lesions caused by obstruction to the juxta-aortic glands are rare. On the other hand, in areas of low endemicity (microfilaria-rate below 10 per cent.) as for example in Allahabad, the common types of lesion are lymph-varix and chyluria, elephantiasis being rare; whereas in moderately endemic areas (microfilaria-rate between 10 to 20 per cent.) one finds all types of filarial disease. It has been suggested that this variation in the type of filarial disease is due to the intensity as well as the period of infection in a locality.

For diagnosis of filarial infection, blood examination for microfilaria and eosinophilia is usually relied upon. In addition to these methods recent research has shown that it is possible to detect the presence of the infection by dermal and complement-fixation tests.

Treatment. Treatment for filarial infection may be dealt with under the following headings:—

(1) **Anaphylactoid symptoms.** The production of anaphylactic symptoms varies with individual susceptibility. Every case should be carefully investigated and treated accordingly. In addition, vaccines made from the various strains of streptococci and staphylococci and arsenical compounds such as soamin have been found to give the best results in the treatment of anaphylactoid signs and symptoms.

(2) **Filarial disease.** Lymphangitis, abscess and elephantiasis are the common manifestations of filarial infection.

In a large number of cases the acute attacks are due to secondary infection. When they are caused by streptococci high temperature sets in with a fairly high leucocyte count. When the infection is in the spermatic cord it tends to spread towards the peritoneum and sometimes proves fatal. Staphylococcal infection shows milder reaction—the fever is 101° to 102°F. and leucocytosis is not so high. Pus is often formed with formation of abscess. For acute signs and symptoms, the treatment is symptomatic and consists of rest, ice application, diaphoretics, and local application of sedative lotions like calamine, polyvalent streptococcal sera may also be given. In case of abscess formation surgical treatment is necessary.

In cases of elephantiasis surgical operation for excision of hypertrophied tissue has been recommended. It should be remembered, however, that such operations will not cure the disease. Massage, pressure bandages, prevention of secondary infection and treatment for the same are helpful in reducing the size of the limb and checking its growth. Periodical courses of mixed streptococcal and staphylococcal vaccines have been found to give the best results. In case of genital affection, surgical treatment for the excision of elephantoid tissue is recommended.

Lymph varix. In the early stages application of suspensory or pressure bandages together with treatment for filarial infection is recommended. In advanced cases surgical operation for removal of varix may be necessary.

A large amount of work has been carried out in searching for specific drug for filarial infection, but no success has been attained so far. Many drugs, chiefly compounds of arsenic, antimony, bismuth and copper have been tried without success. Investigations have been carried out with compounds of zinc, lead, tin and gold. Various synthetic and vegetable alkaloids have been tried orally and also by injection, but no success has attended any of these experiments.

Prophylaxis of filarial infection consists chiefly in anti-mosquito measures and isolation of the early infected cases (carriers).

Chyluria, lymphuria or hæmato-chyluria. Blockage by *Wuchereria bancrofti* at the level of (1) the juxta-aortic

glands which drain the lymphatics of the kidneys, or (2) the iliac (internal) glands which drain the lymphatics of the bladder, results in lymph-varix which ruptures on strain or trauma, and leads to leakage of chyle or lymph sometimes mixed with blood. The urine is clear in the morning or after rest but becomes milky after a fatty meal. Cystoscopic and pyelographic examinations are helpful in locating the site and the side affected. Secondary infection is very common in chyluria—culture of a catheter specimen or midstream urine shows streptococci or staphylococci.

Microfilariae are always present in the blood and in urine in cases of chyluria. They are absent in long-standing cases when the parasites are dead. Sometimes they are present only in blood or only in the urine.

Complement-fixation test with the *Dirofilaria immitis* antigen is positive in cases of chyluria. Dermal tests with the same antigen have given negative results so far. Chyluria cases show a constant moderate eosinophilia (above 5 per cent.).

For the treatment of these conditions absolute rest is necessary. Restriction of fats and fluids is essential. The focus or foci should be eradicated, secondary infection treated with autovaccine or stock vaccines (streptococci and staphylococci albus and aureus). Salol, methylene blue, urotropine, picric acid, quinine and potassium iodide have been tried but do not seem to have any specific effect. Astringent injections of Ext. hamamelis liq. or tannic or gallic acid into the bladder give relief. The cautery is helpful in closing the leak in the bladder. Sodium citrate in large doses is given to prevent clotting of chyle in the bladder. The following have been tried with beneficial results:—

Arsenic compounds.

Soamin, subcutaneously, intramuscularly or intravenously; commence with 1 gr. (0.06 gm.) to maximum 3 gr. (0.2 gm.), twice weekly. Total 20-25 gr. (1.3 to 1.6 gm.).

N.A.B., neosalvarsan or sulfarsenol, 4-6 doses.

Tryparsamide, 2 gm. in 10 c.cm. of distilled water intravenously once a week, not exceeding a total of 8 gm.

Antimony compounds.

S.A.T. 2 per cent. solution intravenously commencing with 1 c.cm. and gradually increase to 5 c.cm. twice a week. Total of 2.5 to 3 gm.

Fouadin, 1.5 c.cm., 3 c.cm. and 5 c.cm. intramuscularly or intravenously daily. Total 30 to 40 c.cm.

Urea-stibamine, stiburea or aminostiburea 0.1 gm. to 0.3 gm. in distilled water intravenously twice a week. Total 2.5 to 3 gm.

Neostibosan, 0.1 to 0.3 gm. in distilled water intravenously, daily. Total 3 gm.

ANTIMONY COMPOUNDS

Schistosomiasis. Bilharziasis has been successfully treated by injections of tartar emetic. It was at one time thought that there was no means of destroying these parasites but MacDonagh (1915) first recommended and Christopherson (1918) first tried, and showed that injections of the double salts of antimony are successful in eradicating both kinds of African schistosome infection—*S. haematobium* and *S. mansoni*. Tyau (1922) and Tootall (1923) showed the efficacy of antimony injections against the related parasite *S. japonicum*. The routine followed by Christopherson is to begin with $\frac{1}{4}$ grain (0.015 gm.) doses for children and $\frac{1}{2}$ grain (0.03 gm.) for adults, dissolved in 20 min. of distilled water and then diluted with an equal quantity of normal saline. The dose is increased by half a grain up to $2\frac{1}{2}$ grains (0.1 gm.) unless a reaction is produced before that time. Injections are given every other day, the dosage being kept between 2 to $2\frac{1}{2}$ grains (0.13 to 0.16 gm.) until 25 to 30 grains (1.7 to 2.0 gm.) have been given. This amount is usually sufficient to cure an adult; children are given proportionately smaller doses, the maximum dose being on the basis of 0.003 gm. (3 mgm.) per kilo. body weight. In out-patient clinics in Egypt over a 100,000 patients are treated annually, the treatment used being a course of 12 injections, given three times a week, and totalling 22.5 grains (1.5 gm.) of tartar emetic; this cures 80 to 97 per cent.

of cases. The effects of the treatment are most striking. After a few injections the vesical pain and the scalding sensation disappear. Blood is also absent from the urine though sometimes it may persist a little longer. After the full course the urine becomes clear and normal in colour; this change probably corresponds with the cessation of the activities of the parasites and the cure of the disease. This course is suitable for the early stage of the disease when the patient is in a good state of health. In old-standing cases, where they are weak and emaciated, a less intensive course is desirable. A slight coughing at the end of the injection is not a contra-indication for continuing the treatment, but if nausea, vomiting, abdominal pains, giddiness and diarrhoea supervene the patient should be given a few days rest. If more than 25 grains are required it is better to give a second course after an interval of a fortnight or more. Lampe (1926) gave to out-patients 150 to 250 c.cm. of a 1.0 per cent. solution in 6 to 7 weeks, to in-patients, a more intensive course of 200 to 240 c.cm. in 4 to 5 weeks was given. As a rule no untoward symptoms occurred. Lampe's conclusions are in accord with those of Christopherson and he considers 25 to 30 grains (1.6 to 2 gm.) spread over 6 to 7 weeks the best treatment. It is best to continue treatment for a week or 10 days after all ova and leucocytes have disappeared from the urine after centrifugalising.

Usually after the injections have been given for a week or 10 days, improvement begins." In *S. hæmatobium* the vesical pains disappear, the urine clears up, and so does the scalding sensation when the urine is passed. In the case of *S. mansoni* and *S. japonicum* the blood in the fæces decreases, fever disappears gradually and the asthenia and malaise improve. In favourable cases eggs may disappear in 10-15 days. In severe cases dead ova are passed intermittently for weeks and months after the parent worms are dead. Degeneration of miracidia is seen early, generally after about 12 grains have been given. The ova become shrunken, shrivelled and blackish and later do not hatch out in water. When this stage is attained the parent worm is killed and the ova are sterilised *in situ*. As a rule 30 grains (2.0 gm.) of the tartrate administered

in from 28-30 days form the curative dose. The rapidity and permanence of cure, according to Khalil (1924) are less dependent on the total amount of antimony administered than on a regular tri-weekly series of injections. Re-examinations of patients who have been given a course of 12 injections show that 80 per cent. to 97 per cent. are cured completely.

Mode of action. The drug kills not only the adult worms but penetrates the shells and kills the ova deposited in the tissues. This can be demonstrated by adding tartar emetic to 6 c.cm. of warm water at 133°F. to which a little urine containing ova has been added. It is found that if the antimony salt is not added, the ova begin to hatch out in 4 to 5 minutes and that most of them have hatched out in an hour. If, however, a grain of tartar emetic is added to the water only half the ova hatch out and a good many are found to be dead, half in and half out of the shell. If the concentration is further increased very few embryos hatch out and even the few found swimming do not survive long. Under the microscope one can watch the darting, pulsating, corkscrew movements of the miracidia slowing down in contact with tartar emetic solution. Microscopic examination of eggs voided during injections of antimony show that they have undergone degeneration. It is a curious fact that pentavalent antimony derivatives have no effect in bilharziasis. Hamilton Fairley (1924) showed that the lethal effect of tartar emetic *in vitro* was greatly enhanced in the presence of human serum. Everything points to the fact that tartar emetic is a powerful therapeutic agent in the treatment of all schistosome infections. Even in patients undergoing surgical treatment a course of antimony is desirable.

Relapses. Hamilton Fairley (1924) was of opinion that tartar emetic, in a proportion of cases, merely reduced the parasitic level and converted cases of frank clinical schistosomiasis into passive carriers in whom ova are shed in small quantity and at such irregular intervals as to escape detection on one or more isolated examinations. He tried the drug in *S. spindalis* in goats and got results which suggested that the antimonyl tartrates were less effective than emetine. These results, however, cannot be applied to the human disease and

investigations in Egypt show that emetine is not as effective as tartar emetic. Day (1924) showed that comparatively small doses of antimony (25 grains of tartar emetic) are required to kill the ova present in the tissues, and that reappearance of ova in the urine after small doses, is due to the fact that a sufficient quantity of the antimony salt has been given to kill the ova but not the adult parasites, which have only been temporarily affected by these small doses. Relapses are due to lack of judgment with regard to dosage; if a sufficient quantity of antimony compounds are given no relapses occur. It has been shown that 20 per cent. of cases relapse after 2 years with 0.7 gm., 15 per cent. have viable ova after 1.3 gm.; after a full course of 2 gm. 3.5 per cent. still remain infected. The usual cure rate is 79 per cent. In uncomplicated cases, as a rule, 25 grains (1.6 gm.) produce a complete cure, but the total quantity of the drug varies largely in different individuals and every case should be treated on its own merits. Even in the worst cases the mortality is reduced to half.

Antimony tartrates thus have a strong parasito-tropic action on all forms of human schistosomiasis, but their action on other helminths, even on other trematodes, needs further investigation.

During recent years carbon tetrachloride has been suggested as an adjuvant to treatment with tartar emetic. It is said that after one or more doses of carbon tetrachloride the adult worms show signs of degeneration and it is hoped that massive doses of the drug at long interval, to enable the system to recover from its effect, may eradicate the disease. The following preparations of antimony, in addition to tartar emetic, have been used in schistosomiasis.

Bayer SB 212 is a complex salt of organic antimonyl acid containing 25 per cent. of antimony. It can be given intramuscularly, the site of injection being frequently changed.

Antimosan (Von Heyden 461) is said to be effective against *S. japonicum* but it is expensive. It can be given intramuscularly and intravenously. Its efficacy is doubtful.

Fouadin or neo-antimosan. It is a trivalent compound of antimony containing 0.0055 gm. of antimony in 1.0 c.cm. and it is a pyrocatechin sodium disulphonate compound. It has given good results in schistoso-

miasis; 3.0 c.cm. of the drug are given intramuscularly (in gluteal region). Antimosan is said to be well tolerated. Seven per cent. solution is stable. Course recommended:—first day 1.5 c.cm., second day 3.5 c.cm., third day 5.0 c.cm., and then on alternate days till the fifteenth day to a total of 40 c.cm.

Filariasis. Recent observation in human filariasis shows that antimony compounds have no marked effect upon the embryos in the blood though some observers have thought that the number of embryos in the blood shows a marked decrease. Prolonged trials of the antimonyl tartrates in this disease show that the drug has no effect on the adult parasites. Chopra and Sunder Rao (1929) tried almost all the pentavalent organic compounds of antimony, *e.g.*, urea-stibamine, stibosan, neo-stibosan, etc., in filariasis without any effect. The same is the case with other helminthic infestations, *e.g.*, lung infections (paragonimiasis).

Guinea-worm infection is said to be beneficially affected by intravenous injections of tartar emetic. The worm and the embryos are killed, the inflammation is relieved and as a rule a total of six grains of tartar emetic is said to suffice to clear the infection, though in some cases a longer course has to be given. Sometimes, the injections have the effect of bringing to the surface other guinea-worms, which happen to be in the body. Macfie (1922) treated 23 cases of guinea-worm infection with tartar emetic intravenously giving 1 grain (0.06 gm.) every other day. The drug gave encouraging results in this series but was not infallible. In 14 cases complete expulsion of the worms occurred after 4 or 5 injections; in 10 cases, although the worms were not expelled the inflammatory phenomena in connection with it disappeared. Hamilton Fairley tried antimony tartrates in guinea-worm infections without success, he prefers emetine injections given intravenously.

Trichinosis. Injections of tartar emetic relieve symptoms such as fever and muscular pains. Grove (1925) successfully treated a case but further trials are recommended.

Flukes. Antimonyl tartrates have been tried in the treatment of infection with flukes but the results so far have not been satisfactory. The method of administration and dosage are the same as those used in kala-azar.

EMETINE AND OTHER DRUGS

Schistosomiasis. Although emetine hydrochloride does not kill the bilharzial cercariæ (*S. spindalis*) *in vitro* in 1 in 100 dilutions, in the presence of serum it kills them in dilutions of 1 in 160,000. The lethal effects of both emetine and tartar emetic are greatly enhanced in the presence of human serum.

Intravenous and intramuscular injections of emetine have been used in the treatment of *Bilharzia hæmatobium* by many authorities, and have succeeded in permanently eradicating the infection. Six daily injections of 1 grain (0.06 gm.) each are given, followed by an intermission of six days, when a second series of 6 injections is given. In children doses of $\frac{1}{4}$ gr (0.032 gm.) are often sufficient. No living parasites or ova can be found after the fifteenth injection. Emetine is specially indicated in patients who are intolerant to antimony. The drug acts on the ova which show degenerative changes; it also kills the adult worms gradually. Diamantis (1918; 1921) reported a number of cases of *S. hæmatobium* infection which were cured by emetine injections. He gave the drug intravenously in doses of 0.12 gm., 10 to 12 injections at intervals of 3 to 5 days; 0.8 to 1.05 gm. of emetine in all, produced a cure. It is also effective against *S. mansoni*. In urinary schistosomiasis the length of treatment and dosage are both important. Harkness (1920) gave a total of 14 grains (1.0 gm.) and a further total of 20 gr. without effecting a cure. Cawston (1922) recommended emetine dissolved in 20 minims of a 1 per cent. solution of carbolic acid, intramuscularly for 8 consecutive days and then thrice weekly for three weeks. Cardiac depression occurs in the second and third week but it can be avoided by giving digitalis. He gives emetine in preference to antimonyl tartrates in children and young people in whom it is difficult to get into veins. According to him curative doses of emetine for schistosomiasis is double that given for amoebic dysentery. *S. japonicum* has been cured with emetine injections starting with $\frac{1}{4}$ grain and increasing the dose to 2 grains daily, as toleration developed; two courses of 15 grains each with an interval of one week are recommended. Cawston (1926) held that unless very large doses of emetine are given uninterruptedly emetine cannot be depended on in schistosomiasis. Such doses are very risky and are not to be recommended. Emetine periodide has been recommended in the treatment of *S. hæmatobium* in doses of 1 grain (0.06 gm.) three times a day. The drug does not produce any toxic symptoms and appears to have curative properties. Auremetine given intravenously is also said to be effective.

It will be seen from the above review of the literature that emetine should only be used in those cases of schistosomiasis which are intolerant to antimonyl tartrates or in children in whom it is difficult to find the veins. In cases of intestinal schistosomiasis complicated by amoebic dysentery, emetine is indicated. Its dosage should be carefully regulated and if toxic symptoms appear it should not be continued.

Emetine in other helminthic infestations. Emetine has been found useful in infestations of the liver with *Fasciola hepatica* and *F. gigantica*. Kikilko and Imamura (1920) found daily injections of emetine useful in clonorchis infections.

Emetine injections have been recommended in the treatment of dracontiasis. Tournier (1923) treated 17 cases of this infection by giving emetine intravenously and by the mouth, with good results. This has not however been confirmed by other observers. Emetine in daily injections is said to be valuable in ameliorating symptoms produced in paragonimiasis, but these cases need careful watching for the onset of toxic symptoms. Potassium iodide and tartar emetic injections are preferable.

Emetine preparations have been tried against filarial infections, especially of *W. bancrofti*, but without effect.

Organic arsenicals in helminthic infestations. Some of the organic compounds of arsenic have been tried against intestinal parasites as well as in somatic infections. Given by the mouth stovarsol is said to have a vermifugal action. A 10 per cent. solution of stovarsol has no effect on ascaris *in vitro* but when mixed with intestinal juices it becomes active. Injections of salvarsan have been used against clonorchis. Intravenously, organic arsenicals have been tried against oxyuris as well as guinea worm infections; against intestinal and blood flukes they have been tried without success. Neosalvarsan has been tried in hydatid disease in man without success. Experiments on rabbits show that hydatid material given with salvarsan does not prevent cyst formation.

Aniline dyes in helminthic infestations. The use of aniline dyes as anthelmintics is yet in its infancy. Methylene blue has

been tried against clonorchis in Japan with some degree of success. *In vitro* experiments show that living flukes are susceptible to methyl violet, crystal violet and Nile blue sulphate. Methyl violet given intravenously to dogs stains the liver intensely and is excreted in the bile, but concentrations fatal to the worms are very toxic to the host; Nile blue is even more toxic. Mercurochrome 220 (hydroxymercuric dibromofluorescein) and gentian violet have also been tried in clonorchiasis. The certified gentian violet (either penta-methyl or hexamethyl pararosaniline or else a mixture of the two compounds) is definitely toxic to the worms, and after doses of 50 mgm. per kilo. of body weight, by the mouth, produces a definite decrease in the egg count; smaller doses such as 16 mgm. per kilo. are less effective. With 50 mgm. per kilo., however, symptoms of intoxication characterised by vomiting and loss of weight are produced; 35 mgm. per kilo. produce no toxic effects, but in heavy infections where there is much damage of the liver, 15 to 17 mgm. per kilo. is a suitable dose. In man the results are not so good. Twenty c.cm. of a 1 per cent. solution of gentian violet given intravenously, followed 3 days later by 30 c.cm. caused the disappearance of ova in one case.

Among other dyes, malachite green, brilliant green, crystal violet, fuchsin, Congo red, trypan red, trypan blue and thionin blue have been tried. Both acid and alkaline dyes showed some toxicity on the cysticercus and on the larvæ, but no experiments have been carried out *in vivo*.

PART III

REMEDIES USED AGAINST PROTOZOAL DISEASES

The commonest diseases which are caused by protozoal organisms in tropical climates may be grouped as follows :—

- (1) Amœbiasis (dysentery, etc.).
- (2) Leishmaniasis (kala-azar).
- (3) Trypanosomiasis (sleeping sickness).
- (4) Hæmosporidia infections (malaria and blackwater fever).

From very early times, attempts have been made to influence these diseases by drugs. Countless drugs have been introduced empirically from time to time for the treatment of parasitic diseases only to be discarded after more prolonged trials. The work of Ehrlich opened up a new field for the scientific assessment of the value of drugs. During the years that followed, rapid advances were made in this field of chemotherapeutic research. Helminths, protozoa and spirochaetes can be readily detected by direct examination by the microscope and hence the influence of drugs on these organisms has been studied in an elaborate fashion. Though the mode of action of these drugs has not been clearly explained, certain interesting data have been obtained which are worth recording. Emetine and its derivatives and the cinchona alkaloids have been found to act on some protozoal organisms, while compounds of arsenic, antimony and bismuth have a well-marked toxic action on others. Compounds of mercury as well as aniline dyes show a marked activity against some protozoa, but these have the limitation of being also toxic to the host.

The recognition of trypanosoma infections in experimental animals and their behaviour under the influence of drugs injected or administered otherwise, has made it possible for the scientists to study the mode of action of various remedies under laboratory

conditions. Kolmer has studied the trypanocidal activity of certain remedies on *T. equiperdum* and has shown that different drugs have different degrees of toxicity to this organism.

Name of compounds.	Motility 15 minutes.		Rat inoculation tests.		Results.
	Present.	Absent.	Dilution.		
Trypan red ...	1 in 20,000	1 in 10,000	1 in 10,000	+	
Atoxyl ...		1 in 200	1 in 200	-	
Tryparsamide ...		1 in 200	1 in 200	-	
Salvarsan & Neo-salvarsan ...	1 in 320,000	1 in 160,000	1 in 160,000	-	
Mercuric chloride	1 in 5,000,000	1 in 250,000	+	
Tartar emetic	1 in 10,000,000	1 in 5,000,000	+	
Tartro-bismuthate of sodium & potassium. ...	1 in 200	1 in 100	1 in 100	-	

It will be seen that tartar emetic is strongly trypanocidal *in vitro*, then follow mercury and arsenic preparations. The pentavalent compounds of arsenic are much less active, and bismuth compounds and the aniline dyes are still less. In many instances, in dilutions sufficient to destroy motility, they are trypanocidal in animals, but this is not so in the case of tartar emetic. Loss of motility, however, does not always mean death. In a general way, it may be said that there is relationship between activity *in vitro* and *in vivo*, though of course there are many exceptions. The activity of trivalent organic arsenicals is very high *in vivo* and *in vitro*.

During the last few years, certain definite advances have been made in the chemotherapeutic treatment of protozoal diseases and in the following chapters the present position of our knowledge regarding these drugs will be presented.

Classification of Drugs Acting on Protozoal Infections

(1) *Amoebiasis* and intestinal flagellate infections. Ipecacuanha and its derivatives, *Holarrhena antidysenterica* and its derivatives, yatren, stovarsol, carbarsone, etc. Such drugs as *Plantago ovata* (Isabgul), and *Ægle marmelos* (Bael fruit) have only palliative action.

(2) **Leishmaniasis.** Antimony compounds, Arsenicals, Bayer 205.

(3) **Trypanosomiasis.** Arsenicals; Bayer 205 and Fournieu 309 (Moranyl); antimonials, bismuth compounds, quinoline derivatives.

(4) **Hæmosporidial infections (Malaria).** Cinchona alkaloids, plasmochin, atebirin, malarcan, tebetren.

VACCINE THERAPY IN PROTOZOAL DISEASES

During recent years evidence has been brought forward to show that immunity may develop in protozoal diseases, and in accordance with this hypothesis vaccines have been tried by several workers in the treatment of protozoal infections. It must be pointed out, however, that in contradistinction to bacterial diseases, the phenomenon of immunity in protozoal infections generally is still problematical and vaccine therapy in the latter group is yet in experimental stage.

For the rational and successful employment of vaccine therapy in infectious diseases in general, three conditions need to be satisfied: (1) The ætiological agent of the disease should be one that can be isolated and grown in a form suitable for the manufacture of vaccine; (2) the mechanism of cure of the disease should be one in which the natural processes of defence such as the antibody and the phagocytic mechanisms play an important part; (3) the treatment of the disease with drugs should be in an unsatisfactory state and sufficient experimental evidence present to indicate that vaccine therapy will be beneficial when employed alone or in combination with drug therapy. Applying these three criteria to vaccine therapy in protozoal diseases we find that there is very little need or justification at present for the employment of this therapy in human beings except in a few conditions in which specific drugs of value have not yet been discovered. The following is a brief outline of the evidence on which the above conclusion is based.

Judged from the point of view of the first criterion mentioned above we find that there are many technical difficulties in the way of preparing suitable vaccines out of most of the pathogenic protozoa that infect man. Protozoal organisms compared to

bacteria, are rather difficult to grow *in vitro* in artificial culture media and the only protozoa that have so far been successfully cultivated on a large scale and in a form suitable for vaccine production are *Leishmania tropica*, *Leishmania donovani*, and *Entamoeba histolytica*. Others such as the trypanosomes plasmodia, etc., are not only difficult to grow outside the body but it is also not easy to obtain them in a pure state for vaccine manufacture. The types of protozoal vaccine that have commonly been employed in experimental work on laboratory animals are (a) attenuated living organisms, (b) virulent organisms which after inoculation are controlled by treatment and (c) dead or disintegrated organisms and their products. For use in human beings the first two are unsuited and the third which may prove useful is not available in all cases.

Judged from the point of view of the second criterion, vaccine therapy does not appear to be any more satisfactory. The chief object in injecting vaccines being the elaboration of antibodies for the purpose of destroying the infecting agent, we would naturally wish to ascertain, before employing it, whether (a) there is sufficient evidence to prove that antibodies are formed in protozoal infections, and (b) if so, whether these antibodies play any important part in overcoming these infections. Although our knowledge of the immunity mechanism in protozoal infections is very imperfect, there is some evidence that antibodies are formed in certain protozoal diseases particularly those due to the hæmoprotezoa; but in these diseases there is no certainty that the antibodies elaborated are of real value in immunity. In trypanosomiasis and leishmaniasis, the lytic, opsonic and anti-reproductive antibodies that are formed are supposed to play a part in the overcoming of these infections; but, both on account of the complexity and variability of the antigens present in these organisms as well as due to their possessing powers of adaptation and resistance against the injurious action of antibodies it is not possible to assess correctly the value of antibodies in immunity to protozoal diseases. Furthermore there is evidence to suggest that in other protozoal infections as for example the plasmodium infections, immunity is dependent upon the sensitiveness of the phagocytic mechanism

and also upon certain non-specific factors such as alterations in cell permeability, variations in bio-chemical conditions and in the nature of available food supply. If it is so then it is still more difficult to say how far the use of specific antigens (vaccines) and the presence of specific antibodies can be of benefit in overcoming these infections.

Judged from the third and last criterion, we find again that vaccine therapy in protozoal diseases can at best be only of limited value. The treatment of most of these diseases with drugs is in quite a satisfactory state and there is little need for resorting to vaccines to bring about a cure. In malaria visceral leishmaniasis, amebiasis and trypanosomiasis specific drugs of proved merit are readily available and no practitioner would ever dream of employing vaccines in preference to them.

Taking the evidence discussed above as a whole, the manufacture and use of vaccines so far as the treatment of most protozoal diseases is concerned, may justifiably be said to be a matter of pure research or academic interest. The results of practical employment of vaccines in the different protozoal diseases recorded below further substantiate this view.

Oriental sore. It was noticed long ago that recovery from an attack of oriental sore conferred immunity to a second attack. This observation was put to practical use and individuals were inoculated with material from a sore on certain unexposed surface of the body in the hope that after recovery from the attack of the disease, immunity would be produced and lesions on the face, etc., would not occur and cause disfigurement. The next step to this way was to prepare vaccines from cultures of the organism and try them for prophylactic purposes. Although the results were not encouraging it was realised that immunity developed only when an experimental sore was produced and was allowed to run a natural course. Row (1912) tried the effect of vaccines in the treatment of cases of oriental sore and claimed that he obtained favourable results. Ray employed a vaccine prepared in a different way to Row's (organisms were grown on solid media and killed by freezing and thawing) and claimed that it possessed remarkable curative properties. His claim has not yet been corroborated by others and the matter may be considered to be still in the experimental stage. An extensive use of the vaccine in a well controlled series of cases can alone help in elucidating its real value.

Kala-Azar. Nicolle and others found that recovery from one attack of kala-azar protected dogs and monkeys from another attack. This

led to attempts to treat kala-azar with vaccine and the results obtained by the workers were very unsatisfactory. Longo, Di Cristina and Caronia used vaccines on human cases of kala-azar and obtained very disappointing results. Napier and his co-workers (1932) used a leishmania vaccine supplied by Ray in four cases of kala-azar but the results obtained were not very encouraging. From the theoretical point of view the employment of a vaccine for the treatment of kala-azar does not appear to be either sound or justifiable. There is no evidence that in kala-azar there is a dearth of antibody due to a dearth of antigen.

Dermal leishmaniasis. A vaccine has been employed in this condition but the results have been very variable. While in a certain number of selected cases a small degree of temporary improvement was noticed, in the majority of unselected cases little benefit was obtained. Remedies such as urea stibamine and neostibosan have so far yielded decidedly better results than vaccines. Therefore the latter is worth a trial only when these drugs have failed. At the present stage it is difficult to form a correct estimate of the value of vaccine therapy in this disease; it can neither be condemned as useless nor commended as being very useful.

Trypanosomiasis. The usefulness of vaccine in this disease has been tested only in laboratory animals. Trypanosomes, which have been killed, lysed, dried or attenuated have all been employed but the results obtained are not quite satisfactory. Serological tests conducted after the administration of vaccines have revealed specific changes in the blood serum and complement fixation tests have yielded positive results. From this alone we cannot be certain whether the antibodies present are helpful in protecting the animal from subsequent infections or not. In human cases of trypanosome infections vaccines have not been tried.

Plasmodium infections. In the case of plasmodial infections of birds it has been shown that inoculations into canaries of sporozoites, which have been rendered non-infective by keeping them for 12 to 48 hours after removal from mosquitoes, rendered them immune to inoculation with virulent parasites. In human beings on the other hand the immunity to re-inoculation that develops in the course of malarial therapy of G. P. I. cases, does protect these individuals from infection when sporozoites from mosquitoes are injected.

Piroplasmosis. Vaccination with the living organism followed by treatment with specific drugs has been remarkably successful in prophylaxis.

Babesia infections. Using a vaccine made from macerated spleen and lymphatic glands of animals infected with babesia it has been shown that about 50 per cent. of the animals develop immunity and are resistant to re-inoculation. Vaccines have not been used for curative purposes in this disease.

Conclusion. From the above discussion it will be evident that the use of protozoal vaccines has so far yielded very interesting results from an immunological point of view in laboratory animals but their employment in man as a therapeutic agent has furnished neither successful nor encouraging results. It may be possible that with improvements in the technique of preparation, standardisation and administration of protozoal vaccines we may obtain in future more encouraging and beneficial results; but at the present time their value seems to be very limited, only being helpful in a few selected cases in certain special conditions. The stage is not reached in which one can safely recommend these vaccines as valuable therapeutic agents for the routine use of the general practitioner. They may, however, be used for experimental purposes by specialists in select individual cases.

SECTION I

REMEDIES USED AGAINST AMŒBIASIS

CHAPTER I

GENERAL CONSIDERATION

Incidence of amœbiasis. Amœbic dysentery is common in India. A routine examination of the stools of patients admitted into the Carmichael Hospital for Tropical Diseases showed an incidence of 12 per cent. of infections with *E. histolytica*. According to Knowles (1928) chronic intestinal amœbiasis, as a cause of sickness and invaliding in this country, is of great importance especially among the European community. An acute attack of amœbic dysentery can, in the majority of cases, be successfully relieved by proper treatment, but eradication of the chronic intestinal infection with *E. histolytica* is a difficult matter. Although there are a number of supposed cures for amœbiasis, it may be said that *therapia magna sterilisans* has not yet been found. Most of these remedies reduce the infection to a low level so that the patients' natural powers of resistance can keep in check the parasites which still remain in the body.

The causative organism. A number of amœbæ infest man and animals but they do not all produce disease. All authorities now consider that *E. histolytica* is the pathogenic organism. The pathogenicity of *Entamoeba histolytica* and the harmlessness of *E. coli* in man were shown by Walker and Sellards in 1913. The two organisms look very much alike, but they can be distinguished by the fact that in the protoplasm of *E. histolytica* numerous red corpuscles are present while *E. coli* contains bacteria and other foreign bodies. The cystic stage of the parasitic organism has a thin wall and usually contains four nuclei which can be stained with double strength iodine solution, while fully developed *E. coli* cysts have eight nuclei. The cysts appear in the stool when the acute dysenteric symptoms have subsided and they constitute the resistant stage. The cysts can live outside the body for some days and they cause new infections when swallowed with food. Experiments show that the cysts do not develop in the small intestine but in the upper part of the large where plenty of fluid is present. Dobell (1928)

described the process of excystation with the escape of a single quadrinucleate amoebæ through a minute perforation in the cyst wall. No sexual phenomena have been observed during the metacystic stage. The resistant cysts are the source of new infection which are carried by the housefly or by other means. Most cyst carriers are not healthy and require active treatment to rid them of their infection.

E. histolytica can now be cultured without difficulty on a medium containing human serum, dextrose, NaCl, KCl and NaHCO₃. The culture from stools is of practical value in establishing the presence of the organism when microscopical examinations have failed. Hæmolytic, cytolytic and complement-binding substances have been obtained from the cultures by extraction with alcohol and a complement-fixation test for the diagnosis of *E. histolytica* infections has been worked out.

Non-pathogenic entamoebæ occur in the human intestine. *E. coli* is by far the commonest organism. *Endolimax nana* resembles a small *E. coli*; its oval cyst contains four nuclei. *Iodamoeba butschlii* has a vesicular nucleus and its cysts have a signet-ring-like nucleus with a large and very prominent glycogen vacuole. *Dientamoeba fragilis* shows two nuclei. *E. dispar* can only be differentiated from *E. histolytica* by injection into the rectum of kittens.

Diagnosis. Diagnosis can be made in 75 per cent. of cases by single examination of the stool and in 90 per cent. by two examinations; as many as six examinations may, however, be necessary.

The problem of cure. Dysentery is a clinical syndrome meaning the passage of blood, pus and mucus with the stool accompanied by tenesmus, and the term has been loosely used even to cover the carriers where these symptoms are absent. Some use the word 'cure' in the sense that vegetative and cystic entamoebæ are absent while others use it to mean that the clinical symptoms have abated. The effects of treatment can only be accurately gauged by a careful examination of the stool for the presence of *E. histolytica*; for in amoebiasis a temporary or clinical cure and permanent freedom from infection are unfortunately by no means always synonymous. Some authorities take cure to mean freedom from all symptoms and absence of amoebæ in the stools for at least six months from the cessation of symptoms. This is a difficult test to be of any practical value. In the Military Hospitals during the great war the test for cure officially laid down was six negative examinations during the three weeks following the treatment, the last three examinations being done in the third week. In the Carmichael Hospital for Tropical Diseases six negative examinations on six days after the cessation of treatment are taken as the criterion of cure and for all practical purposes this suffices; moreover, when the patients are relieved of all their symptoms they cannot be persuaded to stay in the hospital much longer. The treated cases are divided into three main groups.

(1) **Failure of treatment.** If either vegetative or cystic forms of *E. histolytica* are present, the treatment has failed.

(2) **Probable cures.** If the examination of six stools after cessation of treatment gives negative results the case is probably cured. These cases however cannot be said to be absolutely cured, but the chances are on the side of a favourable prognosis.

(3) **Indeterminate cases.** If however six stools have not been obtained the case is 'indeterminate,' and the majority of cases unfortunately fall under this head in actual practice.

Latent infection and 'carriers'. The degree of severity of symptoms in an individual infected with *E. histolytica* varies widely. These variations are due to (1) variation in the resistance of different individuals to the inroads of the parasites and (2) variations in the tissue-attacking and tissue-dissolving power of different strains of the parasites. It has been shown that *E. histolytica* is not always a tissue parasite; it can occur in the large intestine without tissue penetration. A latent infection does not always mean ulceration of the bowel, but an ulcerative process may be established at any time. In latent carriers the entamoebæ live in the lumen of the gut and feed on the bacteria present there. They never invade the tissues and produce very mild symptoms. These cases are amenable to treatment.

When actual symptoms of dysentery are present, the amoebæ are numerous and in full activity, they are amenable to the action of emetine. The reason is that the gut in these conditions is hyperæmic and emetine circulating in the blood will have ready access to the amoebæ. The cases most resistant to treatment are the indeterminate group which get relapse after relapse and fail to react to any drug. In these patients there is superficial ulceration or even considerable thickening and fibrosis of the gut, the amoebæ are walled in and it becomes difficult for emetine to reach them. When there is a co-existing infection with bacillary dysentery, especially of the Flexner group, the contents of the gut are very acid and there emetine is not so effective.

Why it is that entamoebæ cause symptoms in one individual and not in another is difficult to explain. The influence of environment on the vegetative forms of *E. histolytica* is an important factor; the stasis of the gut contents and their consistency have a bearing on the encystation of the amoebæ. It is

possible that these factors play a part in the carrier problem and prevent emetine from producing its usual effect

Whenever possible, examination of the ulcer with the sigmoidoscope should be done for diagnosis as well as to see the curative effect of the drug. This instrument is of great practical use in the diagnosis of the latent stages of amœbic dysentery. Ulceration may be present without producing any pain. A healed scar after treatment is a sign that the amœbic activity has disappeared, but when traces of lesions are seen in the small depressions or pits which stud the mucosa, the disease has not been eradicated.

Diet in amœbiasis. The diet is of great importance in the early stages of treatment of acute dysentery. Less food means more rest for the inflamed intestine, but this should not be done at the expense of the patient's strength. For the first few days it is preferable to give fluid diet such as chicken broth, rice water, egg albumin or barley water. Later, milk diluted with lime water and barley water or citrated milk may be given if curds are being formed. When this is well borne pure milk or Horlick's milk or Benger's food may be substituted. Some patients, however, develop a distaste for milk and cannot digest it and such things as rice water (kanji) may be given.

Such strict dietary is not necessary for sub-acute and chronic cases. It is not necessary to restrict the diet of carriers during treatment, but such articles of diet as are irritating or leave a large residue, *e.g.*, vegetables, hot curries, etc., should be forbidden. It is advisable to stop all alcohol and also smoking during the treatment. After the completion of treatment the diet should be gradually increased, milk, puddings of sago, arrowroot, rice, cornflower, custard, etc., being given in place of milk; later lightly boiled eggs and toast or a little soft-boiled rice; fish and white meat should be added gradually.

In addition to diet restrictions, the patient should avoid chill and exposures. The patients who have suffered from amœbic dysentery, even though the infection may be eradicated, are always liable to attacks of looseness of the bowels, the gastrointestinal tract being very susceptible to slight irritations for a long time after.

CHAPTER II

IPECACUANHA AND ITS ALKALOIDS

Ipecacuanha or the 'Brazil root' was used in Brazil as a remedy for dysentery many centuries ago. In 1684, Piso first brought it to Europe. He discovered this valuable drug during his tour of exploration in Brazil and the West Indies, and on his return to Amsterdam he published an account of its anti-dysenteric properties. Piso's discovery failed to attract much attention except in Holland. The efficacy of the drug, however, was noticed by Helvetius who obtained a supply and sold it in Paris as a secret remedy for dysentery. He was fortunate enough to cure the Dauphin, the son of Louis XIV of France and after a few more successful trials, the French Government bought the secret from Helvetius. The remedy then came into use generally, but after its first vogue it seems to have been abandoned for a long time till the beginning of the 18th century when it became popular again. The powdered bark was given in 2 drachm doses with tincture of opium to prevent nausea and vomiting, and beneficial results were obtained in dysentery, tropical hepatitis and other conditions. The value of the remedy as a cure for dysentery became gradually established and in 1912 emetine, the alkaloidal active principle, came into use instead of the root.

The root is obtained from two species of *Cephaelis*, belonging to the natural order Rubiaceae. (1) *C. ipecacuanha* or the Rio ipecac (also known as *Psychotria ipecacuanha*). This is the only form recognised by the British Pharmacopoeia. (2) *C. acuminata* or *Carthagenia ipecacuanha* has a thicker root, its annulations are less marked and it is cheaper. The plant grows about 30 centimetres in height and is found in most parts of Brazil and is also cultivated in Minas Geraes and other provinces of that country. Attempts have been made to cultivate it in other places with some degree of success; from the Straits Settlements (Johore and Selangor are the most important exporting areas) ipecacuanha root of an unusually fine appearance and rich in alkaloidal contents is exported in considerable quantities. In Java and Ceylon the cultivation has not been so successful. Plantations were started in India in the Nilgiris, at Mungpoo near Darjeeling and at Mergui in Burma. The Darjeeling and Nilgiri plantations did not prove a success and have been practically abandoned. The Burma plantation is promising and is expected to yield roots of extremely rich qualities. The British Pharmacopoeia (1932) required that the root should not contain less than 2.0 per cent. of the alkaloids. The United States Pharmacopoeia allows both *Cephaelis ipecacuanha* (Rio) and *C. acuminata* (Carthagenia) to contain 7.75 per cent. of the ether-soluble alkaloids.

From the slender root and prostrated stem, roots are given off at intervals; some of these develop an abnormally thick bark and this thickened bark and thickened root constitute the drug of commerce. The root is gathered during the dry season, quickly dried in the Sun, and sifted from the adherent sand and earth. The official root is slender and tortuous, varying in colour from dark brick red to dark brown. It contains 2 to 3 per cent. of total alkaloids of which two-thirds is emetine; ipecacuanha wood yields about 1 per cent. of total alkaloids.

Substitutes of ipecacuanha in the market (1) *Ipecacuanha stem* has often been found mixed up with the root and much of the drug that is imported is a mixture of the two. It contains 0.97 to 1.8 per cent. of the total alkaloids, the yield being lower than that of the root.

(2) Under the name of East Indian root, the rhizome of a small monocotyledon plant *Cryptocoryne spiralis*, N.O. Aroidæ (Tamil-*Aithi Vadayam*) has been exported from Southern India (Madras), but the root contains neither emetine nor cephaeline. It resembles ipecacuanha root in appearance only.

(3) The root of *Psychotria emetica* or the greater striated ipecacuanha resembles closely the Brazilian ipecacuanha. It has been tried but although it has irritant and emetic properties, it contains no emetine.

(4) The roots of *Richardsonia scabra* occur in tortuous pieces, but they are quite different from those of the Brazilian ipecacuanha.

(5) White ipecacuanha is the root of *Ionidium ipecacuanha* N.O. Violaceæ.

(6) *Trinidad ipecacuanha*. Under this name the rhizome and root of *Asclepias curassavica* have been offered for sale.

(7) *Lesser striated ipecacuanha*. This drug is occasionally found in the market, and appears to be a species of *Richardsonia*.

(8) *Naregamia alata* (tin pari or titvel) grows in Western India and is said to have the properties of ipecacuanha, but it contains no emetine.

Many other roots also find their way into the market but with the exception of ipecacuanha stem none of them contains emetine or cephaeline. The following test for emetine is useful for distinguishing roots which contain that alkaloid from numerous substitutes.

Half a gm. of the powdered root is mixed with 20 c.cm. of strong hydrochloric acid and 5 c.cm. of water and filtered. To 2 c.cm. of filtrate 0.01 gm. of potassium chlorate is added; if emetine is present the liquid assumes a yellow colour changing to red in the course of an hour.

Chemistry of ipecacuanha. In 1817 Pelletier isolated the alkaloid emetine; in collaboration with Magendie its physiological action was determined and in 1829 it was first used in the treatment of dysentery. The discovery of emetine was quickly followed by the isolation of several

other important alkaloids strychnine, quinine and veratrine. These discoveries along with morphine so absorbed the attention of the profession that for the time being emetine was neglected. Pelletier's emetine contained the total alkaloids of ipecacuanha and this name continued till 1894 when Paul and Cownley showed that it consisted of two alkaloids to which they gave the names *emetine* and *cephæline*. Subsequently the same workers demonstrated the presence of a third alkaloid psychotrine which occurs only in small quantities. These three alkaloids are chemically closely related.

Emetine is a white amorphous substance which darkens on exposure to light, gradually assuming a yellow colour. Its halogen salts and nitrates are crystalline, the sulphate and the acetate are amorphous. The hydrochloride which is largely used is a white crystalline powder and is easily soluble in water and alcohol. Emetine is probably an isoquinoline derivative because the latter substance is formed on oxidation with potassium permanganate. It would therefore appear to be related to papaverine and narcotine; in fact some of the opium alkaloids have been shown to have a well-marked toxic effect on protozoa. Emetine is methyl-cephæline; iso-emetine is probably a stereo-isomeride of emetine, but attempts to convert one to the other have so far been unsuccessful. Iso-emetine is considered by some to be a methyl ester of iso-cephæline. Iso-emetine is non-emetic and comparatively non-toxic; it has, little effect in *E. histolytica* infections.

Cephæline is a crystalline alkaloid less soluble than emetine, it is soluble in alkaline solutions and darkens on exposure. By methylation, it is converted into emetine. Cephæline hydrochloride in doses of 1/12 to 1/6 grain is said to be a more powerful emetic than emetine.

Psychotrine is related to cephæline but has 2 atoms of hydrogen less. It is the least toxic of the three alkaloids and has a doubtful therapeutic effect in amoebic infection. On reduction, psychotrine yields a mixture of cephæline and iso-cephæline; these on methylation yield emetine and iso-emetine respectively.

Other constituents. An amorphous alkaloid has also been described as occurring in ipecacuanha. O-methyl-psychotrine and emetamine, two new alkaloids, have been prepared from ipecacuanha root; their proportions are 0.015 to 0.033 and 0.002 to 0.006 per cent. respectively; emetamine on reduction yields iso-emetine. Methyl-psychotrine has no action whatever on *E. histolytica*. The drug appears to be non-toxic to the patient in 2 to 9 grain doses but it is therapeutically inert. Dimethoxy-emetine has been prepared; it is less emetic and its general toxicity is also small. It can therefore be given in much bigger doses but it is less efficacious therapeutically than emetine.

Besides the three main alkaloids there is also another constituent, ipecacuanhic acid, which at one time was considered to be responsible for the action of ipecacuanha in dysentery. It has been shown however that

it is inactive. A crystalline glucoside ipecacuanhin has also been found in the root.

PHARMACOLOGICAL ACTION OF EMETINE

Amœbicidal action. Vedder (1911) found that emetine in dilutions of 1 in 100,000 killed living amœbæ in broth cultures and pointed out that 1 in 10,000 dilutions killed *E. histolytica* in pieces of mucus in stools, while 1 in 100,000 solution rendered them quite inactive in 3 minutes. Emetine was also said to be lethal to free-living amœbæ in dilutions up to 1 in 200,000 if the exposure was sufficiently long. *Entamœba gingivalis* is paralysed in culture by a 0.25 per cent. solution in four hours. Rogers (1912) confirmed Vedder's work and found that emetine was a very active drug, which attacked and quickly killed *E. histolytica* in dilutions of 1 in 100,000. He tried hypodermic injections of emetine hydrochloride in the treatment of amœbic dysentery with excellent results. Dale and Dobell (1917) demonstrated that even 1 per cent. solutions failed to have any effect on *E. histolytica* obtained from scrapings of the intestine of kittens infected with dysentery. The action is weak so that the encysted and the more resisting forms are not affected whereas the vegetative forms are killed. Allan (1920) found that emetine in dilution of 1 in 250 failed to kill *E. histolytica* in the stool of dysentery patients. Dobell and Laidlaw (1925) tested the action of ipecacuanha alkaloids on cultures of *E. histolytica* and found that emetine and cephæline of all the substances tested were able in very weak concentrations to kill the amœbæ, if allowed to act for a sufficient length of time. They prepared a special liquid medium for growing entamœbæ and added known quantities of the alkaloids to the tubes and thoroughly mixed them. The tubes were then inoculated with amœbæ and incubated for 2 or 3 days. These experiments made it clear that emetine even in dilutions weaker than those met with in the body after administration of a therapeutic dose had a toxic effect on *E. histolytica*, provided it was allowed to act long enough and the reaction of the medium was not too acid. Cephæline was also found to be definitely toxic for *E. histolytica*. Chopra and his colleagues found that *E. histolytica* present in mucus flakes lost their vitality and were eventually killed by emetine in dilutions of 1 in 200,000, provided the medium was alkaline.

It has been pointed out lately that there is a resemblance between *E. histolytica* and *Balantidium coli* in their reaction to emetine and cephæline; emetine has been shown to have curative effects in balantidial colitis.

Local action. The drug is a local irritant. Applied to the skin in high concentrations in the form of liniment it produces redness, itching and occasionally a pustular eruption; 1 in 500 solution causes marked irritation of the mucous surfaces. Some individuals are extremely sensitive to these effects and in them, urticaria and dermatitis may be pro-

duced by systemic administration of emetine. Application of a 1.0 per cent. solution to the abraded skin may produce a weal. When it comes in contact with the cornea it sets up a painful keratitis. Subcutaneous or intramuscular injections cause edema and hyperemia of tissues and extensive capillary hæmorrhages in the muscle fibres round the site of injection. Unlike the cinchona alkaloids, no necrosis of tissues is observed and the action appears to be mainly on the walls of the capillaries and arterioles. A violent irritation of the bowels can be set up by irrigation with a 1 in 10,000 solution of emetine hydrochloride. Half a grain taken by the mouth produces nausea, quickly followed by vomiting in about an hour; an hour later loose stools are passed accompanied by griping. Much larger doses than can be borne by the mouth, are tolerated by injection without producing nausea, vomiting and diarrhœa; the effect would therefore seem to be purely local.

After injection, emetine can be detected in the stomach and intestines. Large doses of emetine given by injection cause swelling and congestion of the mucous membrane of the whole of the gastro-intestinal tract, which is often covered with mucopurulent secretion or studded with ecchymoses. In the dog, ulceration of the gut has been produced by giving emetine subcutaneously.

Gastro-intestinal tract. Chopra and his collaborators (1928) have shown that emetine inhibits the action of ptyalin even in 1 in 200,000 dilutions. Peptic digestion is, however, stimulated by concentrations stronger than 1 in 2,000, higher dilutions having no effect. Proteolytic and lipolytic digestions are inhibited by concentrations below 1 in 10,000; higher dilutions accelerate these. On the digestion of starch the action of this alkaloid is somewhat inhibitory. Emetine increases the tone of the non-striated muscle of the gastro-intestinal tract, the movements of the gut are stimulated, the effect being more marked as one passes downward from the stomach to the colon. It was also shown that the action was on the musculature directly and not through the nervous mechanism.

Circulation. On the heart of both cold-blooded and warm-blooded animals emetine has a markedly toxic effect. It depresses the excitability and conductivity of the heart muscle and produces slowing and dilatation of this organ resembling that produced by chloroform. The heart becomes irregular, auricular and ventricular dissociation may be produced, and death may occur from ventricular fibrillation, the heart stopping in diastole. In animals intravenous injections of large doses produce a marked fall of blood pressure; after small doses the pressure soon regains its normal level. The fall of pressure is due partly to the direct toxic action of the drug on the heart, but vasomotor paralysis is an important factor especially after large doses. In man there is an appreciable fall of blood pressure to the extent of about 20 mm. of mercury after an intravenous injection or after repeated doses by other

routes. Characteristic emetine pulse (weak, rapid and compressible) and cardiac irregularities of various types are seen after a series of injections of this alkaloid. The isolated heart is slowed and weakened by both emetine and cephaeline and it finally stops in diastole.

Non-toxic doses, while they lower the carotid pressure in animals, produce a rise in the pressure both in the pulmonary artery and vein. Larger doses dilate the pulmonary vessels. The coagulation-time of the blood is not altered though some think it is delayed. Emetine is toxic to the capillary endothelium producing petechial hæmorrhages; local application of emetine also gives rise to capillary hæmorrhage.

Respiratory system. There is some depression of the respiration after subcutaneous injections of the alkaloid, but after intravenous injections the respiratory centre is stimulated and the frequency and the depth of the respiratory movements are increased. Small doses increase the secretion of the respiratory passages and thus act as an expectorant. To this is added a slight relaxation of bronchial musculature which makes the removal of mucus easier. If toxic doses are given they have a decided tendency to cause pulmonary congestion or hæmorrhagic pneumonic consolidation.

Nervous system. In the frog, emetine causes a slowly advancing central paralysis. In mammals, neuritis is produced and there is general depression of this system giving rise to lethargy. The nerve cells especially those of the anterior cornua are damaged first and then the fibres degenerate; there is evidence that the motor fibres are specially picked out. Emetine has a powerful mental depressant action in man. Painful neuritis somewhat similar to that produced by alcohol has been observed.

Uterus. Emetine is said to produce stimulation of the uterine movements, but in dilutions such as those occurring in the body after its administration it has little or no effect.

Absorption and excretion. Emetine and the allied alkaloids are rapidly absorbed from the mucous membrane and the subcutaneous tissues, and are eliminated by the gastro-intestinal tract and by the kidneys. Elimination of emetine by these routes is demonstrated by the effect the drug produces in urinary and intestinal schistosomiasis. A part of the drug appears to be excreted by the bile which probably accounts for its curative effect in hepatic schistosomiasis and liver flukes.

Excretion by the kidneys is discontinuous and prolonged. The drug appears in the urine 20 to 40 minutes after hypodermic injection of a therapeutic dose, but during the course of treatment not more than one-sixth of the drug is excreted by this route. Elimination proceeds by fits and starts, active periods alternating with periods when little or none is found in the urine. The elimination in patients who have received 0.15 to 0.58 gm. in 3 to 8 days may last for 5 to 9 weeks, showing that it forms stable deposits in the body (Mattei 1920). In some cases the drug appears to have been retained for periods ranging

from three months to a year. Large doses irritate and produce inflammation and albuminuria together with chloride and nitrogen retention. The excretion of uric acid is increased by emetine as it is by other gastro-intestinal irritants.

Toxicity. The toxicity of emetine for lower animals has been worked out. By subcutaneous injections the lethal dose for dogs and cats varied from 0.003 to 0.005 gm. per kilo. body weight. If 0.003 gm. is taken as the maximum tolerated dose (corresponding to 0.210 gm. for a man of 70 kilo. or 145 pounds), it is apparent that the adult dose of $\frac{1}{2}$ to 1 grain is well within the margin of safety, provided the number of injections is restricted to 12 to 15. If this amount is exceeded and a much larger number of doses are given it is liable to produce severe reaction and even death.

With large doses, the changes produced in the tissues are of an acute nature, and immediate death within 24 hours may be produced with one single large dose. Doses of 0.05 to 0.075 gm. per kilo. in dogs, and 0.02 to 0.15 gm. per kilo. in rabbits, guinea-pigs, rats, etc., are rapidly fatal. With medium doses the pathological changes are more marked, more time being allowed for their production. With smaller doses it takes longer to produce the same pathological changes, indicating a cumulative action of the drug. There is probably no threshold of safety when the drug is taken continuously.

Emetine attacks all tissues and therefore is a general protoplasmic poison; changes in the kidney, liver, heart and skeletal muscles are identical, all showing hyperæmia, cloudy swelling and degeneration of the cells. The nerves do not show any detectable pathological change till the parent nerve cells are in a state of advanced degeneration. As animals do not manifest pain, probably the motor fibres only are affected. The only lesion seen in transverse section of the cord is degeneration of the anterior horn cells. Some authorities consider that the weakness of the muscles produced after emetine injections is due to the toxic action of the alkaloid on the protoplasm of the muscle fibres.

Pharmacological action of other alkaloids of ipecacuanha. The physiological actions of emetine and cephæline are very similar. Eggleston and Hatcher (1916) showed that cephæline is more irritant and about twice as toxic and emetic as emetine; their parasitocidal action on the entamoeba is about equal. It is generally stated that emetine has a stronger expectorant action and is a stronger nauseant than cephæline; its depressant action on the heart and its irritant action on the kidneys are more marked. Psychotrine is much less toxic but is likewise less parasitocidal. Ipecacuanhic acid, ipecacuanhin and various cephæline esters are more or less inert.

CHAPTER III

EMETINE IN AMŒBIASIS

Ipecacuanha has long been known as *Radix antidysenterica*. One of the chief uses of ipecacuanha is in the treatment of amoebic dysentery, and though emetine has largely replaced the powdered root, the latter is sometimes employed as a supplement to emetine injections. In old days, when ipecacuanha root was used, large quantities of the powder had to be given and it was difficult to avoid nausea and vomiting. Opium and morphine were employed to prevent those unpleasant accompaniments; powders were also used with keratin or salol coating which prevented the drug being dissolved in the stomach and allowed it to pass on to the duodenum, setting free the alkaloids in the intestines. These methods have now been superseded by the introduction of alkaloid emetine. Tull Walsh (1891) in a paper on the rational treatment of acute dysentery gave an account of the excellent results he had obtained with an average dose of one grain of emetine in 24 hours by the mouth. Vedder (1912) showed experimentally the high amoebicidal power of this alkaloid, both on the saprophytic and pathogenic amoebæ. Rogers (1913) started hypodermic injections of emetine as a routine treatment of dysentery and found that it had the effect hoped for by Vedder. Trials were initiated on a large scale and it was found that, though almost a specific for amoebic dysentery, it had little effect on the bacillary form. The oral administration of the powdered root was combined with emetine injections as it was thought that by this method the bowel could be thoroughly permeated with the alkaloid.

It may be said that both emetine and cephæline, when given in adequate doses, produce a prompt disappearance of all the clinical symptoms of an acute infection with *E. histolytica*, and often a permanent disappearance of this organism from the stools. When given by the mouth, however, they produce nausea and vomiting and are often not retained. Emetine has

therefore to be administered in the form of injections and it preferably should be given intramuscularly on account of the tendency it has to produce local inflammations and hæmorrhages after hypodermic injections.

(1) The literature on the use of emetine in the treatment of amoebic dysentery is very extensive, various writers giving different quantities and in different set courses. Knowles (1928) summed up these papers and said that the general consensus of opinion appears to be:—(a) that emetine injections are by far the most satisfactory immediate line of treatment of amoebic dysentery, but (b) that emetine therapy is generally a failure in the treatment of the carrier condition. It has been shown that primary malaria, as therapeutically induced in the treatment of general paralysis of the insane, is a disease which is readily amenable to quinine treatment; only a few days of quinine treatment are necessary to effect a cure without relapses. On the other hand, the experience of all workers in the tropics is that established and relapsing malaria is very difficult to eradicate. Possibly a similar state of affairs exists with regard to amoebic infection of the gut; the prospects of eradicating the infection by emetine therapy may be much better in patients seen when suffering from the first attack of amoebic dysentery than in cases where the infection has become chronic and is well established. In a series of 32 acute and chronic dysentery cases which had 6 to 9 grains of emetine by daily injections of 1 grain each, the ratio of probable cures to failures worked out as 1 : 1.7. The cost of treatment roughly estimated was 2 to 3 rupees per head. These results are similar to those obtained by other workers. Emetine injections undoubtedly eradicate an infection with *E. histolytica* and apparently the alkaloid is more effective in acute amoebic dysentery than in cases of chronic amoebic colitis. In the majority of chronic infections, however, the injections do no more than clear up the symptoms and these patients generally become carriers.

(2) Rogers (1929) recommends daily injection of 1 grain for not more than seven or eight days. He follows the treat-

ment by 20 to 30 grains of ipecacuanha with 10 grains of tannic acid (to lessen the danger of vomiting) and a drachm of mucilage in one ounce of water, to be taken last thing at night before going to bed, and repeated each night for a week. By this method the organisms in the tissues as well as those in the bowels are acted on by the drug.

(3) Deek's treatment consists in giving emetine injections combined with large doses of bismuth salts orally. Knowles (1928) analysed a series of 55 cases treated with daily injections of emetine combined with one drachm of bismuth carbonate by the mouth every day. The patients were suffering both from acute and chronic symptoms, the majority belonging to the latter class. The ratio of probable cures to failures in this series was 1: 1.8. These results are not very encouraging but there appears to be little doubt that bismuth treatment, in combination with emetine injections, from the clinical point of view at any rate, gives good results. The results so far as eradication of the infection is concerned are disappointing.

(4) Emetine injections have also been used in combination with such other drugs, as *Holarrhena antidysenterica* bark, yatren, stovarsol, etc.

Acute and sub-acute amœbic dysentery. The following procedure for treatment of such cases has been recommended by Acton and Knowles:—The patient is kept strictly in bed and made to use the bed pan. A saline purgative is given in the morning to flush the colon; some prefer to give an initial dose of castor oil or castor oil combined with opium (castor oil $\frac{1}{2}$ oz. or 15 c.cm., tincture of opium 15 minims). The diet should be light, chiefly milk or boiled fish. Emetine injections are either given alone or combined with bismuth by the mouth, 1 to 2 drachms of bismuth carbonate is given every four hours in half a glassful of water during the day, with the object of decreasing the acidity of colon and increasing the alkalinity of the portal blood. Some recommend a heaped teaspoonful (180 grains) of bismuth subnitrate in a tumbler of water every three hours night and day in severe cases. Two and a half hours after the first dose of bismuth an injection of 1 grain of emetine hydrochloride is given. The timing of the injection is important as it has been

shown that emetine acts best in an alkaline substrate and that the alkalinity in the portal vein rises about that time. This treatment is carried on for nine consecutive days. For the next three days emetine and bismuth are suspended and only a saline purgative is given. The complete treatment with saline, bismuth and emetine is again repeated for 3 to 6 days. The stools should then be examined for at least 6 consecutive days, preferably 8. This is not always possible for the patient thinks he is cured as soon as the symptoms abate and leaves the hospital.

In case of acute or subacute types of amoebic dysentery, the author has obtained very satisfactory results by the following line of treatment. The patient is kept confined to bed with a flannel abdominal binder and put on light liquid diet, preferably barley water or lime whey. Emetine is given intramuscularly in 1 grain doses daily for six consecutive days. After an interval of three days, a second series of three injections should be given in daily doses of 1 grain. Bismuth carbonate in two drachm doses thrice daily is given throughout the course.

In acute cases with severe pain and tenesmus give a hypodermic injection of $1/6$ grain of morphia, or a small enema of opium and starch (tinct. opii 40 minims or 2.5 c.cm., mucilage of starch 1 oz. or 30 c.cm.). Hot applications to the abdomen such as turpentine stupes, or poultices consisting of linseed meal with a little mustard are soothing. The patient should be kept warm.

Emetine in relapsing and chronic dysentery. Chronic and relapsing amoebic dysentery is one of the common diseases of the tropics and one of the most difficult to treat. Theoretically emetine should be an ideal drug against amoebiasis, as after injection the alkaloid is excreted in the gut and should thus destroy most of the amoebæ. In actual practice, however, it has not proved uniformly satisfactory and a large number of cases relapse. It is said that emetine cures about one-third of the cases; one-third apparently improve and in the remaining one-third the drug has no effect at all. Brown (1926) at the Mayo Clinic found ipecacuanha and its derivatives effective in 58 to 70 per cent. of cases as shown by repeated examination of

stools. The reason for this failure in some cases is the fact that, although emetine acts on the amœbæ lodged in the tissues of the intestinal wall, it has no effect on the parasites in the lumen of the gut. It is known that non-pathogenic amœbæ like *E. coli* remain on the surface of the mucous membrane and possibly *E. histolytica* may do the same though, as a rule, the parasites are found in the tissues. They gain access to the radicles of the portal vein and are carried to the liver where they set up hepatitis and abscesses. Local applications such as colonic irrigation are therefore ineffective. The deeply situated organisms are only reached by emetine through the blood stream. Unfortunately in long-standing cases fibrosis is set up and the capillaries are cut off, thus preventing the access to the parasites of the drug circulating in the blood. Entamœbæ lying in the necrotic or fibrotic tissue (which is avascular) are thus liable to escape the action of emetine. This is the reason why many chronic cases are not amenable to treatment. The second factor is the infection of the ulcers with *B. coli* and other intestinal bacteria which further promote these pathological changes and lead to the chronicity of the lesions, thus hindering the curative action of emetine. Association with dysentery bacilli is not uncommon and some observers go so far as to say that the lesions of amœbic dysentery are not due to *E. histolytica* alone, but to a combination of amœbic infection with some bacterial organisms. Recently, chronic and relapsing cases of amœbic dysentery have been found to be associated with *Bact. pseudocarinatus* which is said to be a phage-modified variant form of Flexner bacillus. The presence of this bacterium along with *E. histolytica* undoubtedly intensifies the symptoms and renders cure more difficult. *B. mucosus* has been cultivated from the ulcers of a number of fatal cases and Acton has pointed out that streptococci play an important role. For these reasons infection with entamœbæ if not treated thoroughly in the early stages is always likely to pursue a chronic course, when it requires prolonged treatment.

Briefly the difficulty of curing chronic amœbic dysentery is due to four factors:—

- (a) Emetine is a toxic drug and it is not possible to give

it in sufficient amounts and over sufficiently prolonged periods to destroy all the parasites. Chronic infections are resistant to treatment though relief of symptoms occurs in the majority of cases. (b) Emetine cannot be brought into contact with amœbæ deeply seated in the ulcers by colonic irrigation. (c) The presence of secondary bacterial infection is an additional factor in preventing cure. When amœbic and bacillary dysentery especially of the Flexner type co-exist, the reaction of the gut becomes very acid and emetine cannot exert its full therapeutic activity. (d) In bacillary dysentery (Shiga type) the reaction of the gut may be alkaline to litmus (pH 8.11), in the amœbic form the pH of the stools is 6.3. It is found that when the pH of the contents of the gut is 7.0 the amœbæ are dead or dying; cyst formation occurs when the pH of the contents is 7.24; Charcot-Leyden crystals are passed at 6.96. The acid reaction hinders emetine which acts better in an alkaline medium. Attempts at markedly raising the alkalinity of the contents of the large intestine by giving alkalies by the mouth have not met with much success. The drugs which decrease the acidity of the contents of the large intestine are compounds of bismuth, preferably bismuth carbonate. (Deck's method).

If energetic treatment is not started in the early stages before extensive destruction of tissues has taken place, relapses are almost certain to occur. There is little doubt that the secondary bacterial infections probably account for most of the cases of failure with emetine. Resistant chronic cases of amœbic dysentery are not infrequently benefited with vaccine, made from such organisms as streptococci, dysentery bacilli, etc., previous to emetine injections. Emetine is much more efficacious in the early than in the later stages of dysentery. The drug is only feebly active against the encysted amœbæ, which though themselves quite harmless, indicate active vegetative forms in the tissues. In cases of relapse, a course of emetine bismuth iodide, 3 grains daily for 12 days may bring about a cure. Dobell and Low (1922) recommend a 'double course' of this drug—3 grains (0.2 gm.) daily for 24 consecutive days, but in the writer's experience in India

very few persons can tolerate such large doses. In the Carmichael Hospital for Tropical Diseases, Calcutta, a course of 1 grain of emetine daily for 10 days was successful in curing a large number of chronic cases of amoebic dysentery. An alternative method is combined treatment with emetine hydrochloride by injection and emetine-bismuth-iodide by the mouth. Emetine hydrochloride is given in one grain doses with emetine-bismuth-iodide 2 grains daily for 6 to 9 days. Even this proved a failure in quite a large percentage of cases. James and Deeks combine emetine injections with bismuth subnitrate, one heaped teaspoonful (180 grains) 3 or 4 times a day, which may be continued for 2 to 3 months after the injections have been stopped. It has been shown that emetine fails to prevent cyst formation especially when the atmospheric temperature is high. Encysted parasites therefore occur in the gut for long periods.

In a number of cases the infection is not eradicated and often the cure is only an apparent one, cysts and Charcot-Leyden crystals being present in the stools. When infection is not eradicated the patient may suffer now and then from attacks of amoebic diarrhoea, or he may have constipation alternating with periods when he passes blood and mucus with stools. A patient in the carrier condition may at any time develop acute amoebic dysentery. An infected person frequently suffers from periodic attacks of acute amoebic dysentery when only the large tissue-invasive forms of *E. histolytica* are present in the stool. Between the attacks when acute symptoms have abated, the carrier condition is maintained. In such cases the courses of both emetine and emetine-bismuth-iodide will have to be repeated after a suitable interval, allowing for all the emetine to be excreted which usually takes 1 to 2 months after a course. The drug treatment of amoebic dysentery should be controlled wherever possible by sigmoidoscopic in addition to microscopic examinations.

Fletcher and Jepps (1924) carried out autopsies on amoebic dysentery cases, and found evidence of the healing power of emetine on amoebic ulcers. In the majority of cases a 12 days'

course of emetine is sufficient to ensure complete healing of the ulcers.

There is no doubt that patients passing *E. histolytica* cysts, especially those who show thickening and tenderness of the cæcum as a result of repeated attacks, should be submitted to repeated treatment with emetine because they have active amœbic lesions as can be demonstrated by the sigmoidoscope. In the cases of healthy cyst carriers discovered on routine examination treatment is not necessary. Due care, of course, should be taken regarding the disposal of their fæces to prevent the spread of infection.

Amœbic hepatitis and liver abscess. Duncan (1902) stated there was no relationship between tropical liver abscess and any form of dysentery. Rogers (1902) showed that living *E. histolytica* could always be found in scrapings from the walls of such abscesses and further that clinical and post-mortem evidence showed that they were secondary to dysentery, always of amœbic origin, but commonly limited to the cæcum and ascending colon which usually gave rise to no symptoms at the time of liver abscess formation. He was of opinion that open operation should be avoided as it always led to secondary septic infection. Chevers (1886) first advocated large doses of ipecacuanha treatment combined with aspiration of liver abscesses on a scientific basis. Later, emetine injections replaced ipecacuanha.

Presuppurative hepatitis. The acute type of hepatitis is easily recognised, and in this emetine gives striking results. In this type aspiration is dangerous and may produce fatal results from internal hæmorrhage. Acute hepatitis with multiple small abscesses is indistinguishable clinically from the above condition. The liver is riddled with scores of small abscesses varying from the size of a pea to that of a walnut. These may clear up under emetine treatment.

Chronic presuppurative amœbic hepatitis is difficult to diagnose and frequently goes on to abscess formation if care is not taken. The liver may not show any tenderness or pain and active dysenteric symptoms are nearly always absent. There may not even be a history of dysentery owing to very limited ulceration confined to the cæcum. In the majority of fatal cases

of liver abscesses Rogers found a very slight degree of amœbic ulceration and in some cases only scars of former ulcers. Leucocytosis with a marked increase in the polymorphonuclear cells is always present and often the condition is only recognised from this. In the absence of fever where leucocytosis is present the condition should be suspected. X-rays may be of value in diagnosis but they do not always reveal abscess formation when it is present in the liver substance. This presuppurative stage may last for a month or longer. Amœbic hepatitis is common in areas where amœbiasis is endemic. According to some authorities 'tropical liver' which is neither amœbic nor alcoholic in origin may result from residence in a hot climate and for this treatment with ammonium chloride is recommended. Such a procedure would be dangerous and it is advisable in all doubtful cases to begin with emetine. That large amœbic abscesses are absorbed under emetine is supported by post-mortem evidence of extensive scars in the liver. Undoubtedly large bulging abscesses diagnosed by putting a needle and drawing out pus have cleared up under emetine.

The fully developed abscess is usually circumscribed by a dense fibrous wall which prevents further destruction of the organ. In certain very acute and actively spreading abscesses there is no limiting wall, small points of suppuration in the branches of the portal vein invaded by living amœbæ are seen round the irregular cavity. The amœbæ are found in an active stage in the wall of the abscess, those which are cast off soon die. This is the reason why living amœbæ cannot be found in the pus, but they can always be found in the scrapings from the wall. These amœbæ are destroyed by injections of emetine. The mortality from liver abscess was very high in pre-emetine days owing to the inevitable secondary infection after an open operation.

Amœbic liver abscess. It has already been observed that emetine is excreted in the bile; it therefore acts on the entamœbæ present in the liver. In amœbic hepatitis, commonly met with in India, emetine is a powerful agent preventing the development of an abscess. After the formation of an abscess, some authorities maintain that it is necessary to aspirate the pus and inject

emetine hypodermically till 7-12 grains have been given. Others consider aspiration unnecessary and say that the pus is absorbed after emetine injections. Cases of amoebic abscess of the liver have undoubtedly been successfully treated with emetine injections only. Manson-Bahr and others have recently confirmed that emetine therapy can by itself promote absorption of pus from a liver abscess without surgical interference. Amoebæ, it is held, are killed in the liver by emetine. The abscess in the active condition has a zone of hyperæmia round it and so long as amoebæ are alive the flow is from this zone towards the abscess. As soon as the amoebæ are destroyed by the action of emetine, the current as regards the abscess is reversed, and the result is absorption and extinction of the abscess. The absorption of sterile pus is in no way detrimental to the patient. There is no doubt that the incidence of abscess of the liver has considerably decreased since the use of emetine in amoebic hepatitis. Neither the gravity of the condition of the patient nor the size of the abscess are contraindications to treatment with emetine. The only disadvantage is that the absorption sometimes takes several weeks and this may weaken the patient. The only indication for surgical interference is the presence of bacteria in the aspirated fluid. It is very rare to find bacteria in unopened abscesses and when they are present the conditions are probably not amoebic but due to extension of a suppurative process from the peritoneum or pleura.

That emetine has some stimulant action on the liver cells can be judged by the fact that it has a beneficial action in other conditions where functions of this organ have been deranged. The writer has found emetine useful in chronic hepatitis of malarial origin, catarrhal jaundice and chronic congestion of the liver due to causes other than heart and kidney diseases. The cholagogue action attributed to emetine has not been confirmed by experiments.

Emetine, however, has been wrongly used in conditions simulating amoebic abscess of liver for want of proper diagnosis. The author has seen cases of chronic malaria given 20 to 30 injections of emetine because the symptoms resembled those of amoebic hepatitis. Although rigorous scientific proofs regarding the

existence of primary amœbic infection of the lung and bladder are not forthcoming, emetine injections cure these conditions when *E. histolytica* is found in them. Amœbic cholecystitis has been proved by finding amœbæ in the pus from the gall bladder.

DOSAGE AND MODES OF ADMINISTRATION

Dosage. The treatment with emetine must be continuous if it is to be efficacious. It must be prolonged for a sufficient period and the dosage should be adequate. Intermittent treatment with small doses or only for a few days may relieve acute symptoms but will not eradicate infection. On the other hand it should be remembered that emetine is a highly toxic substance and if given in large quantities it may produce severe diarrhoea, heart trouble, great prostration and even collapse and death. The consensus of opinion at the present time is that under no circumstances should more than twelve injections of one grain each daily be given in one course, as they are liable to produce toxic symptoms. In the majority of cases 9 injections suffice though many authorities prefer a larger number. The course can however be safely repeated after an interval of 3 to 4 months. Deutsch (1928) recommends for 6-months-old infants a dose of 0.01—0.02 gm., for one-year-old 0.03—0.05 gm., total quantity up to 0.12 gm.; for yet older infants up to 0.15 gm. by injection. As the drug is excreted slowly from the system, with continued administration the dose should gradually become smaller. Vomiting may result but is not serious. The dose must be smaller for weak infants. Cawston (1929) thinks that prolonged administration of relatively small doses of emetine is more to be feared than a few heroic doses and that the immediate toxic effects of the drug are less dangerous than those due to cumulative action. The use of larger doses on alternate days has therefore been suggested, as this would enable the system to recover from the toxic effects of one dose before the next is given and thus avoid further doses as soon as the earliest signs of cumulative action are recognised.

By mouth. Oral administration of ipecacuanha powder was recommended in old days to follow the course of emetine injections; 20 to 30 grains of the powder were given with 10 grains of tannic acid in a drachm of mucilage and an ounce of water, three hours after a light meal and before retiring. This was repeated every night for one week. The usual practice was to begin with a larger dose such as 30 to 40 grains (2 to 2.7 gm.), then to decrease it nightly by 5 grains until a 5-grain dose was reached, which was continued for a week or longer if necessary. As a rule nausea and vomiting were constant accompaniments. About the middle of the course diarrhoea with canary yellow coloured stools appeared and this was looked upon as a favourable sign. In acute cases blood and mucus rapidly disappear and after the course the stool becomes normal. As the root powder contains many superfluous ingredients and is as irritant as emetine, it has now-a-days been superseded by the pure alkaloid.

Emetine hydrochloride is as effective when given by the mouth as by any of the other routes; it is completely absorbed from the gut. Various devices have been adopted to reduce or abolish its nauseating or emetic effects. Unfortunately these have never succeeded without at the same time diminishing or annulling its therapeutic action. Pills and tablets coated with keratin, stearin, salol or other insoluble substances usually minimise the nauseating effects of emetine, but these may not dissolve in the gut and therefore produce no therapeutic effect. The best method of giving emetine by the mouth is as emetine-bismuth iodide. If emetine has to be given by the mouth the dose should not exceed $\frac{1}{4}$ grain. The drug has been administered in various ways, the object being to hurry its passage through the stomach so that the nauseating and emetic action of the alkaloid is avoided. Fuller's earth adsorbate or alkresta tablets have been recommended by some. Keratin-coated tablets have to be used at night before going to bed, the same precautions being taken as in the case of ipecacuanha treatment. Sometimes a certain amount of tolerance develops—the patient retaining the drug after rejecting it for the first 2 or 3 days; 10 to 15 minims of tincture of opium administered previously may

diminish or abolish vomiting. As a rule in acute cases where the patients have to be kept in bed, injections are the best; in chronic cases with slight local lesions the oral method may be employed. Administration of ipecacuanha direct into the duodenum by catheter has been tried.

Per rectum. Good results are said to have been obtained by enemata of 4 to 8 gm. of ipecacuanha powder suspended in a pint and a half of water. Sellards and Levia (1923) strongly advocated the administration of emetine per rectum and recorded actual work on experimentally infected kittens. Colonic irrigations of 0.1 gm. of emetine in 1,000 c.cm. of water or saline have been employed but they are irritating. Preparations like 'emetol' and 'paremetol' for rectal administration have been put on the market. This method, however, is not very suitable for private practice and its practicability also appears to be doubtful, because in man such injections under ordinary circumstances would not go much further than the splenic flexure. Besides, emetine is very irritant to the mucous membrane without having greater amoebicidal virtues *in vitro* than quinine, silver nitrate, etc. This method therefore is not recommended in ordinary cases.

Subcutaneous and Intramuscular injections. Emetine is given either subcutaneously or intramuscularly. The drug is less irritant and painful when given by the latter route owing to smaller number of sensory nerve endings there. Acton and Chopra (1924) showed that emetine injections in rabbits produced oedema and congestion of the tissues at the site of injection, and extensive petechial hæmorrhages but no necrosis. Many authorities recommend $\frac{1}{2}$ to $\frac{1}{4}$ grain (0.02 to 0.03 gm.) as the average dose for an adult by daily injections. The total in any series of injections should not exceed 12 grains on account of the cumulative effects and especially the production of polyneuritis. Some individuals develop an idiosyncrasy towards the drug, a considerable amount of pain and stiffness being caused when given by any of these routes. The symptoms last for several days, and even when injections are given into the loose cellular tissue of the abdominal wall, considerable redness and small hæmorrhages are found at the site of injection in spite of

all precautions to secure proper sterilisation of the skin and needle while other patients under the same conditions develop no trouble whatsoever. These facts should be borne in mind in the treatment of individuals who are not confined to bed, as pain and stiffness may prevent the patient from using his arm for several days. Pain caused by emetine is diminished by dissolving it in a 1.0 per cent. solution of carbolic acid.

Intravenous route. This method was rarely employed formerly but it has come into vogue recently. As early as 1913 intravenous injections of emetine were tried; but toxic symptoms were not uncommon; these consisted of dyspnoea, vomiting, diarrhoea, very slow pulse, unconsciousness and muscular paralysis. Petzetakis (1924) advised emetine intravenously in the treatment of severe cases of amœbiasis; beginning with 0.03 to 0.05 gm. on the first day, and reaching a maximum of 0.1 gm. on the fourth day, a total of from 0.5 to 0.6 gm. of emetine was given in 10 days. In chronic cases also good results have been obtained.

The drug when given by this route should be well diluted and administered very slowly. The dose should not exceed $\frac{1}{4}$ to 1 grain (0.015 gm.) dissolved in at least 10 to 20 c.cm. of sterile saline. Concentrated solutions have been given but weaker solutions are preferable. It is advisable to have an ampoule of adrenalin ready so that it can be given at once if there are signs of cardiac depression or vasomotor paralysis. Some authorities give $\frac{1}{2}$ to 1 grain, nine injections being followed by an interval of 6 days, after which 6 more injections are given making a total of 15 grains. Intravenous injections are likely to be followed by nausea and vomiting which may supervene $\frac{1}{2}$ to 1 hour after administration. The results are said to be rapid and striking and superior to those from intramuscular or subcutaneous injections. De Castro and Deuskar (1927) found that intravenous injections did not give any better results than subcutaneous and intramuscular injections and the experience of the author is the same. Intravenous injections undoubtedly throw more strain on the heart and they should be given with caution especially when that organ is diseased.

CHAPTER IV

COMPOUNDS OF IPECACUANHA AND EMETINE

As emetine, when given by the mouth, produces vomiting, certain insoluble preparations which pass through the stomach unchanged without liberation of the alkaloid have been introduced. Besides these, certain preparations for rectal use have also been prepared.

(a) **Emetine adsorbate or Alkresta Ipecac.** (Lilly & Co.) Alkresta ipecac is the trade name given to an adsorption compound of the total alkaloids of ipecacuanha with hydrated aluminium silicate (Fuller's earth). It is made up in tablets, each of which contains the total alkaloids of 10 grains of ipecacuanha, U.S.P. The advantage claimed for this form of emetine is that it passes through the stomach unchanged and the alkaloid is liberated in the alkaline intestinal contents. This is doubtful. It is now claimed that some of the emetine is dissolved in the intestine in some other way, perhaps by the bile or soaps present there and is absorbed. No exact data are available but it is said that the clinical as well as systemic effects of this form of emetine are not marked. The dosage recommended is 2 to 3 tablets three times a day.

Allan (1916) treated 10 cases with alkresta tablets and found the drug unsatisfactory on account of the variation in absorption from the intestinal tract. He thought emetine subcutaneously was twice as effective. Stephen and Mackinnon (1917) treated 81 cases, all carriers. They gave 10 tablets daily for 14 days, 5 in the morning and 5 in the evening. They concluded that the drug gave better results than injections of emetine hydrochloride. Macgregor and Frew (1922) treated 15 cases of old-standing chronic infections with 2 permanent cures. They gave 30 grains orally combined with daily injections of emetine. Knowles (1928) in a series of 7 cases found alkresta on the whole unsatisfactory. The drug could occasionally eradicate infection with *E. histolytica* but on the whole the results were disappointing. The drug is well tolerated by the patients and its administration is not followed by nausea or vomiting as is the case with emetine bismuth iodide. It is best given at bedtime and is a suitable preparation for private patients. It is worthy of trial in chronic amoebic dysentery.

(b) **Emetine-bismuthous-iodide (E. B. I.).** Dose 3 grains (0.2 gm.) containing approximately 1 grain (0.06 gm.) of emetine. Tull Walsh (1891) first thought of combining emetine with mercury and iodine and made emetine-mercurous-iodide. He

treated 22 cases with this compound but the results were not satisfactory. Du Mez (1915) manufactured emetine mercurous iodide and emetine-bismuthous-iodide and suggested, as results of his experiments on dogs, that these two compounds might be given in large and frequent doses, which would enable emetine to come in contact with *entamoebæ* for prolonged periods. Emetine-bismuthous-iodide is a brick-red powder, insoluble in water. In acidulated water it does split to a certain extent, as is evident from the fact that in 0.2 per cent. solution of hydrochloric acid an opalescence is noticed. The double iodide is perfectly stable in air. According to Du Mez's calculations it contains 58 per cent. iodine, 12 per cent. of bismuth and 29 to 35 per cent. of emetine.

It is advisable to give the double iodide as a loose powder in a hard gelatine capsule or paper cachet. It should not be given in hard or compressed tablets or mixed with insoluble excipients such as vaseline, soap, stearin, etc., nor should it be coated with keratin, salol or other more or less insoluble substances. Experience has shown that unless properly protected it is liable to be dissolved in the stomach giving rise to the usual irritant symptoms of emetine. Even keratin coating was found to be uncertain as nausea and vomiting were produced. In the presence of the alkaline contents of the duodenum the compound readily decomposes, loses its red colour and becomes opalescent white. A 3 grain (0.2 gm.) dose of the insoluble salt containing about one grain of emetine, is the average dose and 10 to 12 such doses are to be given in succession. Indian patients can rarely stand more than 2 grains daily. This is the standard 'full course' which was found to be very successful. Some prefer to give the drug in cachets of one grain each three times a day until 36 grains (2.4 gm.) have been given as larger doses very often are not tolerated. Vomiting when it occurs does not come on as a rule until some time after the dose, indicating the probable liberation of emetine from the intestine and not from the stomach. It is recommended by some authorities that the dose be given after a full meal when the stomach contents would certainly be acid, and on the whole administered in this way the drug is well tolerated.

Others prefer to give it on an empty stomach, and are of opinion that it causes less nausea. The dose should be given at night when the patient is in bed and resting quietly, preferably with a cup of hot tea or arrowroot. The patient should endeavour to sleep and the saliva should be wiped from the mouth or expectorated and not swallowed. In many cases there is vomiting on the first night, but this does not matter if the powder is not rejected; on the second night there is usually little or no vomiting. Throughout the course there is a tendency to slight vomiting in many patients though a certain amount of tolerance does undoubtedly develop for the drug. If nausea or vomiting becomes troublesome it is necessary to give 15 minims (1.0 c.cm.) of tincture of opium, or chlorodyne, or omuopon $\frac{1}{6}$ of a grain, half an hour before each dose. Hot applications or a mustard plaster to the epigastrium may also help. To obtain satisfactory results reduction of the daily dose and intermission or shortening of the course of treatment must be avoided and treatment should only be stopped if severe prostration or cardiac depression supervenes. Emulsions of emetine-bismuth-iodide in 1 ounce of liquid paraffin have been tried and are said to have given better results than tablets.

As the treatment of the carriers with emetine or ipecacuanha during the Great War gave very unsatisfactory results, emetine-bismuthous-iodide was investigated. Cats weighing 3 kilograms could stand doses up to 40 mgm. without vomiting. The drug was then tried in 10 human carriers, but it produced vomiting and diarrhoea. Dobell (1918) reported treatment of 11 carriers who had not been cured by injections of emetine. In all these cases the treatment was successful. He showed that an advantage is gained by administering emetine in the form of emetine-bismuth-iodide in chronic cases which have proved refractory to emetine. The effects of treatment are in some cases remarkable and all stages of *E. histolytica*, whether cystic or otherwise, disappear from the stools. Emetine-bismuth-iodide was thought to be almost a specific against *E. histolytica*, and 2 or 3 courses were necessary to effect a complete cure. It should be noted also that if the first course fails to effect a cure a second course consisting of the same amount of drug administered for the same length of

time is practically never efficacious. Both the dosage and the duration of treatment must be increased for the second course. Although undoubtedly failures after such courses have been reported, the chances of curing carriers of *E. histolytica* with this drug are greater than with emetine in the form of any other salt. Treatment must be regulated by carefully watching the patient who should be kept strictly in bed. In acute cases this is not difficult but patients who are carriers and have no definite symptoms may object. If rest is rigidly enforced there is less sickness and there is less liability to heart trouble. Light diet is of importance throughout the course of treatment. Emetine-bismuth-iodide generally produces diarrhœa about midway or a little later in the course; this is often beneficial as it keeps the bowel thoroughly cleared in addition to the specific effects of the drug. Towards the end of the course depression and general weakness are noticeable, and in some cases the heart sounds may become very feeble and irregular. The pulse should be felt daily and when this condition is detected the drug should be stopped. When the course is over the patient quickly recovers, diarrhœa ceases and the stools become solid.

Emetine-bismuth-iodide is thought by some to be less efficacious in acute dysentery than hypodermic injections of emetine hydrochloride, but Dobell and Low (1922) consider the compound to act equally well in acute cases, in carriers, and in all intermediate conditions. Lambert (1918) treated 40 Indian cases in Mesopotamia and came to the conclusion that in acute cases combined treatment, *i.e.*, emetine injection and emetine-bismuth-iodide by the mouth is the best. In relapsing cases and carriers emetine-bismuth-iodide alone is better. He considers that in emetine-bismuth-iodide we have a combination of considerable potency in the treatment of amœbic dysentery, preferably when the amœbæ are assuming their resistant stage. He recommends it in 2 grain doses every night for debilitated patients. Rennie (1922) tried the drug on 87 cases with good results. Delayed vomiting indicates that the drug is beginning to take effect. During the course, diet should be light and restricted. Manson-Bahr and Sayer (1927) state that many which fail to respond to emetine injections respond to

emetine-bismuth-iodide. They are of opinion that the introduction of this drug has considerably raised the percentage of cures in chronic amoebic dysentery. They admit, however, that such treatment is not ideal from the patient's point of view and there is need for a less toxic and more efficient drug. The well-known toxic effects of emetine are also an objection to its use. Jepps had only 12.7 per cent. of failures with 3 grain doses in an emulsion of $\frac{1}{2}$ ounce of liquid paraffin floated in 2 or 3 ounces of water. The degree of tolerance of patients to the drug varied considerably.

It will be seen, therefore, that while emetine-bismuthous-iodide is a useful drug and worthy of trial especially in chronic cases, it leaves a large residue of cases in which the infection is not eradicated even after several courses. The treatment with emetine-bismuth-iodide is drastic but is said to cure 70 to 80 per cent. of cases of chronic carriers. When once a patient has resisted three courses of emetine-bismuth-iodide, it is no use persisting with it. Sometimes combination of the drug with vaccine made from bacteria infecting the ulcers may be useful. It may also be said that, the hope that the relative insolubility of the drug would prevent vomiting, which is a very annoying, tiresome and unpleasant complication in treatment, has not altogether been fulfilled. It is possible that some detail of administration has yet to be discovered which will remove this objection. The drug is very useful in treatment especially of chronic amoebic ulceration and is worthy of trial where emetine injections have not succeeded.

(c) **Emetine periodide** (E.P.I.). The dose is 2 grains (0.13 gm.) thrice daily after food. The course lasts for 15 days. It is usually combined with 5 grains (0.3 gm.) of exsiccated ox bile which is said to increase its action.

This compound introduced by Martindale, contains 38.7 per cent. of emetine and 61.3 per cent. of iodine. In the presence of acids no emetine is liberated, while in the presence of 2 per cent. sodium bicarbonate the compound is decomposed setting free emetine. It is a dark purple crystalline powder, insoluble in water and physiological acid (0.2 per cent. HCl); it is readily soluble in acetone and slightly soluble in alcohol, chloroform and ether. Clinical experience shows that it is the least toxic of the emetine preparations and as much as 120 grains have been given in 20 days without toxic manifestations, which not un-

commonly occur with emetine-bismuthous-iodide. It is said to be as effective as emetine-bismuth-iodide. If necessary, the course can be repeated after ten days. From the patient's point of view it is more satisfactory than emetine-bismuth-iodide, as nausea, vomiting, depression and weakness are almost entirely absent. Willmore (1923) tried it in a number of refractory cases with good results. He considered it desirable to combine it with medication per rectum especially in those cases where ulceration of the lower bowel is present. It has been combined with stovarsol; it has also been given in sprue, cholera, typhoid fever, etc. Its oral use is said to clear up the urine in children intensely infected with *S. haematobium* as rapidly as emetine injections. Emetine periodide, however, does not cure every case of the disease and when once a person has resisted 3 courses of the drug it is of no use persisting. In amoebic dysentery an intensive course of 90 grains in 15 days is suggested, repeated if necessary, after 10 days. For use in the tropics, a preparation of emetine periodide in dried milk has been recommended (1 grain in 2 drachms of milk), two teaspoonfuls of this being taken in 30 ounces of warm water.

Emetine periodide has been used by many clinicians along with a course of emetine injections. Such a course consists of six injections of emetine, 1 grain each on alternate days combined with 2 grains of emetine periodide concurrently given three times a day with 5 grains of ox bile in separate capsules for 15 days. Given in this way the drug is said to be more effective and less toxic than emetine-bismuth-iodide, and superior to emetine, yatrien or stovarsol alone. The consensus of opinion is that it does not eradicate infection in most of the chronic cases. The drug is, however, worthy of trial and is especially suitable for private patients.

(d) **Aur-emetine** is a combination of periodide of emetine with the aniline dye auramine. It contains emetine 28 per cent., auramine 16 per cent. and iodine 56 per cent. It is a dark maroon coloured powder, insoluble in water. Aur-emetine was prepared by Martindale, and like emetine periodide is practically insoluble in the acid of the stomach. It is split up slowly by the alkali of the upper part of the intestine liberating emetine and auramine. Experiments with the drug showed that 20 per cent. was decomposed in four hours in physiological alkali at 40°C, but it is possible that decomposition is more rapid in the intestine as its administration is quickly followed by orange-coloured faeces. Brown (1926) using a suspension in gum found the growth of free-living amoebae inhibited to the same extent as with emetine and conessine under the same conditions.

In amoebic dysentery aur-emetine is said to be a further advance upon emetine periodide. The use of this drug is not attended with nausea, vomiting, abdominal pain or purging; it is also less depressing than

emetine. It is given in gelatine capsules in doses of one grain (0.06 gm.) four times a day after food on alternate days for seven days, and then daily up to a total of 40 to 60 grains. Stovarsol 4 grains a day on alternate days and rectal injections of 'emetol' may be combined with it, especially in chronic cases. When the liver is involved it is combined with injections of emetine. Given subcutaneously it is less depressing than emetine and therefore the patient need not be kept rigidly in bed.

(c) **Emetol** was introduced by Willmore and Martindale. It is a solution of emetine base, 1 grain (0.06 gm.) in 2 drachms (8 c. cm.) of olive oil and is used for rectal administration. Two drachms of this are added to 4 to 6 drachms (16 to 24 c. cm.) of ether and 8 ounces (230 c. cm.) of olive oil and this is injected slowly after a preliminary wash-out. The foot of the bed should be raised, as far as possible, during the injection. Injections are given every other day, five to twelve making a course. Beneficial results are claimed from the use of this drug, but it is difficult to administer and is not liked by the patients. The effect appears to be purely local. Probably a certain amount of emetine is absorbed when 'emetol' is given per rectum but the quantity cannot be large.

Par-emetol is a suspension of 1 grain of emetine in 2 drachms of liquid paraffin. This is given in 1 to 2 drachm doses at night with a drachm of sodium bicarbonate; the same precautions are taken as in the case of emetine-bismuth-iodide.

(f) **Arsemetine** is a solution of acetyl-amino-oxyphenyl-arsinate of emetine, a well defined chemical compound. One cubic centimetre of the solution contains 4 centigrams ($\frac{2}{3}$ grain) of hydrochloride of emetine and 0.92 centigrams ($13\frac{1}{4}$ grains) of arsenic. Physiological experiment shows that tolerance of emetine is enhanced by the presence of arsenic so that it is possible to administer larger doses. The dose is from 4 to 8 centigrams ($\frac{2}{3}$ to $1\frac{1}{4}$ grains) of emetine, that is to say, 1 to 2 c. cm. of Arsemetine.

(g) **Gavano**. Recently, another derivative of ipecacuanha has been prepared and introduced by Messrs. Bayer-Meister-Lucius under the name of Gavano. It is apparently a derivative of emetine (mono-methyl-esters of cephaeline) or cephaeline itself in combination with an organic acid, the nature of which is not disclosed. The drug is recommended to be given by the mouth in doses of 1 tablet thrice daily for 6 consecutive days or 1 tablet twice daily for nine consecutive days. It does not give rise to nausea and vomiting usually produced by emetine. The proportion of probable cures to the failures in the series of author's 18 cases was 1: 1.66.

Ravaut's Paste has the following composition: bismuth carbonate 100, wood charcoal 100, ipecacuanha 4 to 6, syrup 100, glycerine 100.

The dose is 2 to 10 table-spoonfuls given alternately with 0.1 gm. of nova-arsenobenzol for 10 to 20 days. It has no positive curative effect but possibly keeps in check the distressing symptoms.

Total alkaloids of ipecacuanha in amoebiasis. Roux (1923) employed subcutaneous injections of the total alkaloids of ipecacuanha with good results. In view of the fact that the amoebicidal action of emetine and cephaeline is about equal, the use of the total alkaloids of ipecacuanha in the treatment of amoebic dysentery is worthy of trial. The cost of treatment could be considerably reduced if the total alkaloids could be employed instead of the purified emetine.

In comparing the effects of the hydrochloride of emetine and of cephaeline on patients, Rogers came to the conclusion that though cephaeline hydrochloride both by itself and in combination with emetine, gave results far superior to the oral administration of ipecacuanha powder but judged from the general improvement in the condition of the patient and the disappearance of amoeba from the stools, it was distinctly inferior to an equal quantity of pure emetine hydrochloride. Cephaeline is more irritant and about twice as toxic and hence has never been widely employed.

Other uses of ipecacuanha and emetine. Ipecacuanha has been employed as an emetic and expectorant in the treatment of inflammatory conditions of the respiratory organs. For this purpose it is of course prescribed in very small quantities. Ipecacuanha increases the secretion of the bronchial mucous membrane. The increased secretion may be of service by protecting the inflamed and irritable surface of the mucous membrane from cold air and thereby lessening cough. The effects probably are purely reflex. It has also been employed as a diaphoretic. Emetine has been recommended for tuberculous hæmoptysis, but neither the clinical results nor its pharmacological action justify its use for any internal hæmorrhage; moreover some authorities believe it to be contra-indicated. Emetine has also been recommended in pyorrhœa alveolaris; it may produce improvement by destruction of *E. buccalis*, but it fails to cure this condition because this amoeba only occurs as a secondary infection and is not the cause of the disease.

Emetine has been used in the treatment of a number of other diseases. It has been unsuccessfully tried in syphilis, trypanosomiasis and bacillary dysentery. It has also proved useful in the treatment of metazoan diseases particularly in various types of schistosomiasis.

Acton advises injections of emetine in one grain doses in the treatment of leucoderma. He believes that in addition to its action on *E. histolytica* which is a common infection in these patients, the drug has a depressing action on the functions of the adrenals which are hyperactive in leucoderma.

Emetine in 1 grain doses has been given in sprue, but it produces no beneficial effects.

In pellagra it has been recommended when there is slight indication of buccal infection; 6 daily injections of $\frac{1}{4}$ grain (0.03 gm.) of emetine are given; after two weeks the course is repeated. If the mouth remains sore, four or five courses may be tried.

Emetine has been tried in *oriental sore*. Usually 20 minims of a 5 per cent. solution of emetine hydrochloride in distilled water are injected at the base of the sore round its thickened margins. Inflammation is set up and in 3 to 4 days the sore becomes a well-defined ulcer which is then treated on surgical lines. Emetine has no specific effect either in dermal or visceral leishmaniasis; the effect is purely a local irritant one.

CHAPTER V

TOXIC EFFECTS OF EMETINE

In adult human subjects the figures for immediate massive toxicity are not known. Fatal results however are to be feared with doses of 0.6 gm. and anything above a dose of 1.2 gm. is probably fatal at once. Eleven doses of 1.9 grains each would probably cause considerable damage in a man weighing 12 stone, while 35 doses of 0.8 grains each would be definitely risky. There should be long intervals (three months) between series of injections or courses to allow the drug to be excreted from the body.

No general disturbances or gastro-intestinal symptoms are produced in man when a therapeutic dose is given by injection; local reaction as a rule is small when the solution is neutral. Larger doses cause nausea, vomiting and diarrhoea. As much as 0.25 gm. has been given for a single dose without producing any other symptom except persistent nausea. But if a very large dose of emetine is given the patient may suddenly faint and death may occur from paralysis of the heart. In more slowly developing cases there is persistent nausea and vomiting, diarrhoea, vertigo, extreme muscular weakness and expiratory dyspnoea; the pulse is at first slow and then rapid. Death results from exhaustion, gastro-enteritis or intercurrent inflammation of the lungs. It should be remembered that there may be wide differences in the toxicity of various commercial samples of emetine.

Cumulative toxic effects of emetine. Those who have had experience of treating amebic dysentery cases are alive to the possibilities of the toxic action of this drug. Low in his series of cases, noticed diarrhoea secondarily arising during treatment with emetine and suggested that its unduly prolonged use in too high dosages might eventually produce symptoms of intoxication. It is however very difficult to determine by clinical observation alone, whether the local effects on the alimentary

canal and the general effects of toxæmia are to be attributed to emetine, or to the condition which had led to its administration. Dale and Dobell (1917) performed some very interesting experiments on healthy animals to elucidate this point. They used chiefly rabbits and cats and employed doses which in proportion to the weight of the animals would be regarded as rather too high for continued administration in man. The average weight of an adult man being taken as 65 kilograms, a dose of 1.0 mgm. per kilo. body weight is equal to about one grain for such a patient. Cats weighing 3 kilograms in these experiments were given doses of 5 mgm. which works out to $1\frac{1}{2}$ grains for an average man.

Such a dose given once only had no perceptible action of any kind on the animal and it could be repeated up to a point without any deleterious effects. If however the doses varying from 3-10 mgm. were continued for a fortnight, sooner or later symptoms of intoxication appeared and became rapidly intensified with persistence of the daily injections, leading to a fatal termination. In rabbits, a profuse diarrhoea attended with rapid emaciation was the prominent feature; in cats these symptoms were of secondary importance and sometimes were altogether absent, but lethargy and somnolence were marked and deepened to a terminal coma. The toxic effects consisted of pronounced gastro-enteritis, acute nephritis, oedema of the lungs, weakness and paralysis of muscles. Post-mortem examination showed damage to the liver and kidneys in addition to signs of intestinal irritation; the heart was pale and flabby. The results are very significant and clearly show the cumulative toxic effect of the drug in these animals. They demonstrate the serious danger of pushing emetine beyond a certain point and ought to serve as a warning against the indiscriminate and unguarded use of the drug.

Clinical experience has also established the fact that emetine is a cumulative poison in man. The dosage and the length of time during which it should be given have therefore to be very carefully considered. Formerly, untoward effects from its use were put down to the disease itself and this accounts for such diagnosis as post-dysenteric heart failure. Recent investigations

have shown that undoubted cases of sudden failure of the heart caused by emetine may occur. The depressing effect of the drug, if given in doses of one grain daily for some time, is very marked, the noticeable features occurring after 4th to 6th injections being loss of appetite, nausea, vomiting, abdominal pain and diarrhoea due to gastro-intestinal irritation. Among the serious symptoms of poisoning are an increased pulse rate, listlessness and cardiac depression. There may be general lassitude, disinclination to make an effort, weakness of the legs, tremors of muscles, globus hystericus, cardiac arrhythmia, low blood pressure and a feeling of faintness. General œdema, petechial hæmorrhages, purpuric skin rashes, hæmoptysis and signs of cerebral and pulmonary œdema may also be present. Albuminuria sometimes occurs. Polyneuritis is common and in some cases difficulty in swallowing and a feeling of constriction about the throat and chest have been noticed. Urticaria and large pruriginous plaques persisting for a month after the last injection have been known to occur even after a few injections. Sudden collapse and death may supervene in some cases. Auscultation of the heart in these cases shows similarity of sounds, and a lack of the muscular element in the first sound. Cardiac stimulants should be used at the earliest possible moment when the signs of cumulative toxic effects have appeared. Degenerative changes were noticed by Bais (1923) in human beings after prolonged use of the drug. Chopra and his collaborators (1924) demonstrated that in rabbits marked histological changes occur in the heart after emetine injections. These consist of cloudy swelling, disappearance of the traverse striations and atrophy and fibrosis of the muscle. The author (1934) has shown that degenerative changes are produced in the myocardium after therapeutic doses of emetine which can be detected by electro-cardiographic examination.

Emetine neuritis. Neuritis of the lower extremities is one of the early symptoms and is manifested at first by weakness in the legs, difficulty in walking and interference with the normal reflexes. Usually there is no pain on pressure as the motor nerve fibres only are affected. Wrist drop, ankle drop, toe drop, and hyperæsthesia of the soles of the feet, sluggish

knee jerks and loss of taste are noticed in some patients. It is possible that difficulty in swallowing and the sensations about the throat and chest produced after emetine injections are due to involvement of the nerves supplying those parts; it has also been suggested that these effects may be due to changes in the nuclei in the medulla oblongata similar to those that have been observed in the cells of the anterior horn of the spinal cord. In some individuals symptoms are produced after 8 or 9 grains of the alkaloid. Palsy may develop some considerable time after the cessation of treatment. Fibrotic changes in the nerve trunks have been noted after large doses of emetine in experimental animals, and similar changes probably occur in man.

Emetine has not been found in the cerebro-spinal fluid, but it causes a slowly-advancing paralysis of the central nervous system in frogs. There is experimental as well as clinical evidence to show that peripheral neuritis is produced very early after a course of emetine injections. Emetine does not affect the nerve fibres indiscriminately but has a predilection for those conducting motor impulses. The weakness in the legs seen after emetine administration may also be due to damage of the muscle protoplasm.

Emetine diarrhœa. Emetine when given in considerable quantities produces diarrhœa. It has already been pointed out that in animals emetine may produce gastro-enteritis with hæmorrhages in lymphatic glands, spleen, kidneys and thymus. These experimental animals die even though emetine is discontinued directly the symptoms appear. Diarrhœa which is the first sign of irritation of the gastrointestinal tract was quite common in the old days, the rationale of ipecacuanha treatment being to push the remedy till profuse diarrhœa was produced and the stools became liquid and of a canary yellow colour. After discontinuing the drug the stool assumed its normal consistency and to all intents and purposes the patient was considered cured. Whether the cure was real or not is uncertain as in those days cysts were not recognised. Low (1915) noticed that diarrhœa (occasionally with blood) occurred after hypodermic injections

but not so commonly as when ipecacuanha was given by the mouth. It is not unusual for the patient to get a slight attack of diarrhoea after the sixth injection. Since the oral administration of emetine-bismuth-iodide has come into vogue, diarrhoea has become more common, and when mild this is considered to have a beneficial effect and is not a sign of intoxication. In addition to the specific action of the drug, the bowel is at the same time thoroughly washed out and this mechanical process is valuable as is evident from the successful treatment of bacillary dysentery with saline purgatives. A few days after the termination of the course (3 grains of double iodide for 12 successive days) the stools commence to become solid and in successful cases gradually assume normal consistency.

Cautions and contraindications. Emetine is a protoplasmic poison acting equally on all tissues, heart failure being the actual cause of death. In cases where the heart or kidney is affected, it is advisable to give as small doses as possible for the treatment of dysentery. In otherwise healthy individuals the number of injections should be limited as far as possible, and under no circumstances should more than one grain be given in 24 hours.

Emetine, if administered continuously for therapeutic purposes, depresses the heart, but signs of cardiac depression improve when it is withdrawn. Caution is indicated in all cases where the myocardium is damaged by other diseases such as malaria (malignant form), influenza, diphtheria, etc. It is advisable that the patient should remain in bed during the period of emetine treatment and an accurate record of the pulse rate should be kept. If this is definitely increased, or palpitations occur, the drug should be withheld till the heart resumes its normal rate.

Convalescents who have received a course of emetine should be allowed to leave the bed very cautiously so that the effects of the drug pass off and if the pulse rate goes up, they should return to bed. The author has seen patients whose hearts were permanently strained for want of this precaution. Emetine is a powerful drug and appears to have a selective action on the heart muscle.

Emetine in pregnancy. It has been suggested that emetine should be avoided in pregnancy as it may cause abortion. Some pharmacologists have stated that emetine increases the contractions of the uterus and have issued a warning against its use in pregnancy. On the other hand clinicians have given injections of emetine in advanced cases of pregnancy without untoward results. Recent investigations have shown that after a dose of one grain, assuming that the whole of the alkaloid is absorbed, the concentration of the drug in the blood cannot possibly be greater than 1 in 150,000 to 1 in 100,000. Such dilutions have little effect on the isolated uterus, and if there is any action at all, it is a tendency to relaxation. Acton and Chopra (1923) showed that abortion is more common in cases of bacillary dysentery and is produced by the bacterial toxins; they showed that the toxin of *B. dysenteriae Shiga* is a powerful ecboic. Emetine does not appear to be a causative factor in producing abortion and the coincidence of a miscarriage when injections are being given seems to be due to the toxins of the parasite rather than to the drug. Pregnancy is not therefore a contra-indication to the use of emetine. In menstruating women it is preferable to start the injections after the period is over but in urgent cases treatment should not be deferred.

CHAPTER VI

MODE OF ACTION OF EMETINE

The manner in which emetine acts in amœbiasis has lately been the subject of much discussion. Vedder's observations that emetine hydrochloride in dilution of 1 in 100,000 inhibited the movements of *E. histolytica* were not confirmed by Dale and Dobell (1917). Quinine was found to be more toxic to the entamœba *in vitro*, yet it had not the slightest effect when administered in amœbic dysentery in large doses, whereas emetine was effective in very small doses.

Dobell and Laidlaw (1926) showed that the conclusions regarding the action of emetine on *E. histolytica* had been based on the results of imperfect technique. It was shown that the time of survival of the entamœba outside the body is short and thus the organism can only be given slight exposure to emetine. These results were compared with the therapeutic effects, where the action of emetine on the amœbæ was spread over many days and this was the cause of the disagreement. They devised a technique by which the entamœbæ could be grown on a liquid medium and the action of different concentrations of the alkaloid was observed on the culture which was kept in an incubator for prolonged periods. With this technique quinine concentrations lower than 1 in 1,000 gave cultures of *E. histolytica* as rich as the control. Stovarsol had no effect in dilutions of 1 in 20,000 or less. *E. histolytica* was very susceptible to emetine. In simple liquid medium 1 in 5,000,000 of emetine hydrochloride was lethal for *E. histolytica in vitro* within four days, provided the pH of the medium was about 6.4. With greater acidity of the medium the effect of emetine was much reduced. *E. coli* growing in the liquid medium were killed in dilutions between 1 in 300,000 to 1 in 600,000 with a pH of 6.8 to 7.8. In mixed infections of *E. histolytica* and *E. coli*, emetine eradicates the former leaving the latter free. These experiments demonstrate that the dose of emetine or other alkaloids required to kill *E. histolytica* immediately bears no relation to the minimum dose of the same alkaloid which is eventually lethal, if maintained for some time. A very small quantity of emetine, if constantly present in the intestines for days or weeks, would probably suffice to make life therein impossible for *E. histolytica* though not for *E. coli*. The important conclusion which can be drawn from these experiments is that emetine has a weak amœbicidal action on *E. histolytica* and cures amœbic dysentery by

direct destruction of these organisms. The point worthy of notice is that in order to eradicate the infection, one must aim at maintaining continuously over as long a period as is safe, a sufficiently high concentration to kill the amoebæ. As regards the failure of emetine to kill entamoebæ in the cat, it has been suggested that man and the cat may deal with emetine in different ways. In the cat most of the emetine is rapidly excreted in the urine and not in the gastro-intestinal tract. Some human beings infected with *E. histolytica* appear not to react to emetine treatment. This is not due to emetine-resistant strains, but possibly to the excretion of the alkaloid in larger quantities by the kidneys than by the gastro-intestinal tract.

The other important factor lies in the tissues of the host, and we have to find out if any change takes place in these so as to make it impossible for an obligatory tissue parasite such as *E. histolytica* to penetrate the tissues and obtain the only food on which it can thrive and multiply. It is said that entamoebæ do not touch emetinised red blood corpuscles. Is it possible that the presence of emetine in the tissues of the host prevents this parasite from making use of them for its food? Or is it more likely that the presence of minute quantities of emetine prevents the entamoeba by affecting its mobility or some other function from penetrating into the tissues or using them as food, and thus it dies of starvation?

Be that as it may, there is no doubt that when we attempt to exterminate the protozoal parasites from the body, the administration of a drug like emetine destroys a large majority of these parasites. The body resistance then rises and the patient's own power of resistance finally exterminate the residual parasites. This undoubtedly occurs in kala-azar and appears to hold good for malaria, trypanosomiasis and amoebiasis as well. Two factors, therefore, appear to be concerned in recovery, (1) the natural resistance of the host and his tissues, (2) the moderate amoebicidal action of the drug. A lowering of either of these allows the disease to progress.

CHAPTER VII

OTHER AMŒBICIDAL REMEDIES

HOLARRHENA ANTIDYSENTERICA

It is a small deciduous plant belonging to the natural order Apocyanaceæ. It is also known by the name of *H. codaga*, *H. pubescens*, *H. malaccensis*, *Wrightia antidysenterica*, and *Chenomorpha antidysenterica*. Two species *H. congolensis* and *H. wulfsbergii* growing in West Africa also have a reputation in the treatment of dysentery. In England it is known as bitter oleander, dysentery rosebay, oval-leaved rosebay or conessi bark tree. In Sanskrit it is called *Indrayav* or Indra's seeds, *Kutaja* and *Kulinga*; in Hindi, it is known as *Indrayaba*, *Kureya* and *Dubhi*; in Bengali, *Kurchi* or *Kutrai*; in Persian, *Indrajavatakh*.

The plant is widely distributed throughout the plains of India and Burma in deciduous forests and open waste land, where it is often gregarious. It grows in the valleys of the outer Himalayas up to a height of 4,000 feet above the sea-level, and is abundant in the sub-Himalayan regions. It is also common throughout the greater part of the Indian peninsula down to Malabar and Travancore and grows abundantly in the forests of Burma. *H. antidysenterica* is often mistaken for another species of the same family, viz., *Wrightia tinctoria*, in fact Linnaeus was originally responsible for this confusion. In 1809 Brown revised the whole of the family of Apocyanaceæ and rectified the mistake. In spite of this the two plants have been mistaken for each other. *Wrightia tinctoria* is inert and it is largely owing to this fact that *H. antidysenterica* did not attract much attention, because more often than not the inert bark was used instead of the active Holarrhena. The tree flowers in April to June or sometimes July to August; the fruits are full-sized from August to October and ripen from February to April. The flowers are like those of white jasmine and have a fragrant odour.

Both the bark and seeds of this plant are among the most important medicines of the Hindu materia medica; infusions made from these have been used in the treatment of dysentery for many centuries. The Hindu physicians consider the plant to have bitter, stimulant, antipyretic, astringent and antidyenteric properties. It stops hæmorrhage, is an expectorant and is used as a tonic. It forms part of many preparations in the Ayurvedic (Hindu)

and Tibbi (Mohammedan) medicine. Kanai Lall Dey (1896) was so struck with its therapeutic value that he advocated that it should be included in the British Pharmacopœia.

Chemistry. *Seeds.* The seeds contain 29.36 per cent. of a fixed oil and 0.025 per cent. of the alkaloids.

Bark. As early as 1858 Haines isolated an alkaloid which he called *nerine* from the Linnæan name of the plant, *Nerium antidysentericum*. In 1864 Stenhouse isolated an alkaloid from the seeds which he called *wrightine* after the then commonly accepted name *Wrightia antidysenterica*. Both these names were rejected in 1865 by Haines who called the alkaloid *conessine*. Ranchandra Dutt (1880) gave the name of *kurchicine* to the alkaloid after its Bengali name. The same alkaloid occurs in the two African species mentioned above and Pyman (1919) isolated a new alkaloid to which he gave the name of *Holarrhenine*. Ghosh and his collaborators (1928) found in the Indian variety a second alkaloid in addition to conessine differing from holarrhenine which they named *kurchicine*, and a third alkaloid with a low melting point named *kurchine*. Assay of the powdered bark shows that it contains 1.5 per cent. of total alkaloids by weight; but it is difficult to get conessine in pure condition out of the crude total alkaloids, much being lost in the process of purification. Besides these alkaloids a number of tannins are present in the root.

Pharmacological action. The Pharmacological action of conessine was studied first by Keidel (1878) who found that this alkaloid depressed the centres for conscious sensation and voluntary movements in the brain. The activity of the vasomotor centre was depressed and the reflexes tended to disappear. The alkaloid also increased the peristaltic movements of the intestines and induced contractions of the bladder. Keidel concluded that the action of conessine resembles that of morphine. Warnecke (1888) found that the alkaloid was excreted in the urine of dogs as dioxy-conessine. Burn (1914) stated that both conessine and holarrhenine have a similar physiological action. They both produce a considerable narcotic action in the frog but this action is inappreciable in mammals. They also possess a marked anesthetic action on the cornea. Both the alkaloids produce local necrosis when injected subcutaneously. Both conessine and holarrhenine delay the conduction in the auriculo-ventricular bundle producing inco-ordination and heart-block. The isolated heart of a rabbit comes to a standstill halfway between systole and diastole. In small doses intravenous injections of both alkaloids produce a rise of blood pressure. This rise is still present when the vasomotor nerves are paralysed, so it must be due to the direct action of the alkaloids on the muscles of the arterioles. According to Giemsa and Halberkahn (1918) large doses can be given to man without producing necrosis. Brown (1922) appears to have been the first worker to test the power of conessine, the chief alkaloid of *kurchi*, as an amœbicide. Working with cultures of pond amœbæ

he found conessine to be distinctly lethal and that when it was incorporated with the culture-medium in a strength of 1 in 1,000,000, it inhibited their growth. Experiments with mice showed it to be much less toxic than emetine but subcutaneous administration in medicinal doses, according to him, produced local necrosis. On the other hand, he found that it can be safely given by the mouth in large doses. Henry and Brown (1923) on testing the tannins of kurchi bark and of ipecacuanha against the free-living ciliate protozoon, *Glaucoma*, found both to be highly toxic to this organism. The alkaloids have little or no effect on the bacilli of the dysentery group.

The pharmacological action of conessine has been fully studied by Chopra and his co-workers (1927). It was found to be lethal to *Paramœcium caudatum* in a dilution of 1 in 2,800 of its molecular weight, and in a dilution of M/20,000 in the presence of N/200 NaOH. It killed free-living amœbæ in a dilution of M/1,000 and in a dilution of 1 in 280,000 in the presence of N/200 NaOH. Its action on the vegetative forms of *Entamœba histolytica* was tested on the dysenteric stools of experimentally infected kittens. In mucus flakes in such stools it paralysed the motile amœbæ, in dilutions of 1 in 230,000 in 8 minutes in the presence of an alkali, and in 18 minutes in the absence of alkali. Emetine in dilutions of 1 in 200,000 was found to be ineffective against the amœbæ, but paralysed them if alkali was present. Conessine had but little action upon *Trichomonas hominis*, but was markedly lethal to the coprozoic flagellate protozoon, *Bodo caudatus*. Conessine salts can be given subcutaneously and intramuscularly. Contrary to what was reported by Brown, these workers found that no necrosis of the tissues followed its hypodermic injection. Intramuscular and subcutaneous injections of conessine hydrochloride produce less local reaction and pain than emetine.

The statement of Burns on the action of conessine on the heart muscle, if it were true for the total alkaloids, would make one hesitate to administer them in large doses. Any limitation in the dosage would defeat the end in view which is to attain a concentration of these alkaloids in the large intestine sufficient to kill the *E. histolytica* in spite of the acidity that is present in the gut contents or in the surface tissues. The author and his co-workers therefore investigated the action of these alkaloids in detail.

(a) *Gastro-intestinal tract.* These alkaloids have an inhibitory action on the activity of the digestive ferments such as ptyalin, pepsin and trypsin. The peristaltic movements of the intestines are inhibited. The alkaloids have no emetic action and do not produce nausea.

(b) *On the circulation.* Small doses, 2 mgm. injected intravenously into the saphenous vein of a cat weighing 2 kilo., caused a persistent fall of blood pressure, but without any alteration in the intensity or frequency of the heart beat. In much larger doses,

there was slowing of the heart beat. Perfusion experiments with the isolated heart rarely showed any effect on the frequency or force of the contraction. Doses of 2 to 5 mgm. in a cat of 2 kilo. showed no alteration in the auricular and ventricular contractions as seen in myocardiographic tracings. Although there is a marked rise in pulmonary pressure with conessine and kurchicine, the rise is only slight when the total alkaloids are injected into the animal. The fall in blood pressure is not due to a direct action on the heart or heart muscle.

(c) *The volume of various organs and structures in the body.* The limb volume and that of the liver, spleen and kidney were all decreased after intravenous injections of the total alkaloids, indicating that vaso-constriction was occurring at these sites. On the other hand, there was a very marked increase in the intestinal volume with complete inhibition of intestinal movements; this was recovered from after a few minutes.

(d) *Local effects of intramuscular or subcutaneous injection.* When a 6 per cent. solution was injected into the tissues no hæmorrhage or necrosis was observed, but a good deal of œdema occurred at the site of injection. The œdema was most marked in 24 hours and disappeared completely in 48 hours after the injection; hyperæmia and œdema were due to the acidity of the salt of the alkaloids. One to two grains of the total alkaloids give rise to no signs of hæmorrhage or necrosis such as is seen with emetine or quinine.

(e) *Uterus.* The total alkaloids have very little effect on the excised uterus or on the uterus *in situ* except in strong concentrations which it is impossible to attain in the circulating blood. The alkaloid *kurchine* with a low melting point is the most powerful, causing contractions in a concentration of 1 in 50,000. Most alkaloids circulate in the blood at a concentration of 1 in 500,000 to 1 in 150,000. Therefore these alkaloids would have no effect on a pregnant uterus.

(f) *Excretion.* The alkaloids are mainly excreted by the gastrointestinal tract and by the kidneys. They can be detected in the urine soon after intramuscular or oral administration. The excretion goes on for nearly a week after cessation of the treatment.

The action of low-melting point alkaloids has been worked out by Chopra and his co-workers (1933) and is very similar to conessine.

There is no emetic or depressant effect in man when 20 grains of the bismuthous iodide salt of the total alkaloids are given daily for 10 days. The pulse remains normal in frequency, tension and rhythm. There is no alteration in the heart sounds, even in a case of cardiac disease. The drug does not cause irritation of the alimentary canal like emetine. If it does occur,

this is probably due to a co-existing infection with *B. dysenterica* (Flexner or Strong).

Therapeutic uses. The bark and seeds of *H. antidysenterica* have been used in the treatment of dysenterics of India for many centuries. It appears to be used in the indigenous systems in two forms:—

(1) As kurchi bark, either in the form of a powder or watery extract.

(2) As *India Jav*, an emulsion of seeds. Tull Walsh (1891) refers to the use of the bark as being approximately equal in its effects to emetine mercuric iodide. The drug, however, was not tried properly in the treatment of dysentery until lately. Tablets made from the powdered bark have been put on the market by Barroughs Wellcome & Co., and have been combined with emetine injections. Drake-Brockman (1926) used this drug as an adjuvant to emetine in the treatment of chronic amoebic dysentery with excellent results. Different preparations of the drug have been tried in the treatment of amoebic dysentery.

The drug is now used in one of the following forms.

(1) *Bark*. Sixty grains of the bark in the form of tablets of 1 to 2 drachms of the extract are given orally every day for ten days. The improvement is less rapid than with emetine but seem to be more lasting. These findings are in accord with those of Tull Walsh in 1891. The ratio of probable cures to failures by this treatment in a series of 16 cases was 1 : 1.

Emetine may be combined with *H. antidysenterica* bark. The latter may be given either in the form of powder or extract together with a course of emetine injections. In a series of 9 cases the ratio of probable cures to failures worked out to be 1 : 1.

(2) *Conessine*. One to two grains of conessine are given intramuscularly every day for 10 consecutive days. The drug is well tolerated but the results are not so good as when the powdered bark or the extract is given. Henry and Brown (1923) found the tannins of *H. antidysenterica* bark highly toxic to free-living protozoa and it is possible that the superior action of the powdered bark and the extract is probably due to the presence of these compounds. The ratio of probable cures to failures in a series of 9 patients treated by this method was 1 : 2.

(3) *Total alkaloids*. Injections of total alkaloids have been tried in a number of cases. In uncomplicated acute cases of amoebic dysentery the vegetative forms of entamoebæ disappear rapidly from the stools and as a rule do not reappear. In cases with co-existing bacillary dysentery and in chronic forms of amoebiasis the results are less favourable. Total alkaloids have also been given by the mouth; they do not produce nausea or vomiting.

(4) *Kurchi-bismuthous-iodide*. Acton and Chopra (1929) prepared bismuthous iodide of the total alkaloids of kurchi which they called 'kurchi-bismuthous-iodide'. This double salt is insoluble and can reach the large intestine in sufficient concentration to kill the entamoebæ, if large enough doses are given. The drug can be tolerated in doses of 10 grains twice daily, there being no appreciable effect on the heart or blood pressure, no depressant or emetic effect and no irritation of the gastro-intestinal tract such as are observed in the case of emetine.

The author at first tried the effect of injections of the total alkaloids in 10 cases of amoebic dysentery some of which were acute and others chronic. The drug was given in doses of one grain daily intramuscularly; a marked local reaction was however produced. In this series there was one failure. In another series of 20 cases kurchi-bismuthous-iodide was given twice daily in doses of 4 grains curing 12 cases. Two required a second course; of these one was cured.

It will thus be seen that in acute cases of amoebic dysentery kurchi alkaloids are as powerful as emetine in their immediate effect on the symptoms as well as in their curative value, even in one grain doses. No toxic effects were noticed even with injections of two grains daily except flushing of the face immediately after the injection, but this did not last for more than a few minutes. Some patients complained that they could not sleep after injection of such large doses. The injections were however very painful and had to be given up.

The cause of failure in treatment both with emetine and the kurchi alkaloids is due to secondary bacterial infection of these ulcers by streptococci, *B. dysenteriae* (Flexner), or *Bact. pseudo-carolinus*, etc. These organisms form a large amount of acid from the carbohydrates, which diffuse into the tissues from the gut and also into the gut contents. These alkaloids are ten times more powerful when acting in a substrate at a pH of 8 than when acting at a pH of 6. There are three methods of overcoming this acidity of the gut contents. The first method, and one that seems the most obvious, is to administer large doses of alkalis by the mouth, *e.g.*, one to 2 drachms of bismuth carbonate every 2 to 4 hours, sodium bicarbonate or potassium citrate. These drugs have very little effect in reducing the acidity of the large intestine. Clinical-

ly this method is useless. The second method is to deal with the organisms that are responsible for the production of this acidity by isolating them, preparing a vaccine, and then immunising these patients against their own organisms. In this way it has been possible to alter the pH of the stool from 6.8 to a pH of 7.35 after three weeks of immunisation. That this method is a sound one is shown by Acton and Chopra (1929); even in spite of repeated failures with emetine, cure can be effected by combined treatment with vaccines and emetine. More recently Acton and Chopra (1933) by using the bismuthous iodide compound of the total alkaloids of Kurchi in doses of 10 grains (0.6 gm.) twice daily for 10 to 20 days, preceded half an hour before by a mixture containing one drachm of sodium bicarbonate and 40 grains (2.6 gm.) of sodium citrate, obtained a proportion of probable cures to failures of 3.16 : 1 in a series of 78 cases. In obstinate and persistent cases, a prolonged course (1 to 3 months) of standardized extract of kurchi, 1 to 2 drachms twice daily, with or without *plantago ovata* (Isabgul) is often effective.

The third method is to give the drug in large doses in order to attain a sufficiently high concentration to be effective in an acid substrate. Fortunately, the total alkaloids of kurchi bark are not toxic, so that large doses can be given, and we can also form an insoluble bismuthous iodide compound, which will not begin to act until it reaches the acid substrate in the cæcum and large intestine. This actually does occur, as qualitatively it is found that the kurchi alkaloids appear in the urine of patients taking the bismuthous iodide compound. *Entamæba histolytica* may be living in the tissues or in the lumen of the gut. In the former case, it will be in contact with the serum and body fluids at a pH of 7.2, whilst in the gut the contents may reach a high degree of acidity between a pH of 5 and 6.

It is necessary to explain the somewhat discordant results obtained by different clinicians in the treatment of chronic intestinal amoebiasis with kurchi-bismuthous-iodide. The process of preparation materially alters the alkaloidal content and uniform results are always obtained if the compound is prepared according to the method laid down. In some

cases of failure it was discovered on investigation that the process of manufacture described had been modified, and in order to facilitate the extraction of the alkaloids, hot alcohol had been used instead of the cold as originally recommended. This had the effect of changing the alkaloids, and possibly radical changes were produced in the one with a low melting point which forms the chief constituent. The failures are also to be attributed to the fact that the supply of good fully-matured bark sometimes cannot keep pace with the large demand and consequently large quantities of immature, improperly collected and imperfectly dried bark come into the market. Such barks are sometimes employed for the extraction of the alkaloids used in the preparation of kurchi-bismuthous-iodide. The discordant results so far as kurchi-bismuthous-iodide is concerned, are due to:—

1. Some fault in the procedure of extraction of the alkaloids from the bark or preparation of the compound.
2. The bark from which the alkaloids are extracted not being mature, being improperly collected or being imperfectly dried.

Kurchi-bismuthous-iodide was originally prepared in the Calcutta School of Tropical Medicine on the same lines as emetine-bismuth-iodide by the cold extraction process. Its approximate composition is as follows:—Total alkaloids 27 per cent., bismuth 22.85 per cent., and iodine 50.15 per cent. The dose is 10 gr. twice daily preceded half an hour by an alkaline mixture. In simple cases a course of 10 days' duration is given; when mixed infection exists 15 to 20 days may be necessary.

YATREN

Synonyms:—Loretin, quinoxyl, 'Yatren 105' was prepared by Behring & Co., and is claimed to be 7-iodo-8-hydroxyquinoline-5-sulphonic acid. It is a finely crystalline powder, pale yellow in colour; it easily absorbs moisture, and must therefore be kept dry. It has 36.2 per cent. of sodium carbonate added to increase its solubility. It has no odour, has a solubility of 4 to 5 per cent. in water. When dissolved it is said to become iodine-oxyquinoline sulphate of sodium with the liberation of carbon dioxide. Yatren is said to be almost as good a specific for amebic dysentery as quinine is for malaria but this claim has not been substantiated. In Japan a brand of locally prepared iodine oxyquinoline sulphate of sodium has been used with success in the treatment of both forms of dysentery; it is considerably cheaper than 'yatren 105'.

Pharmacological action. Yatren is claimed to be a cell stimulant and a strong disinfectant. The action of yatren on cultures of *E. histolytica* 'in vitro' has been studied. A solution of 1 in 100 kills amœbæ in a few hours; solutions of 1 in 4,000 to 1 in 5,000 inhibit multiplication and the cultures generally die out. The amœbæ prove resistant to the action of 1 in 10,000 concentrations. Taken by the mouth Yatren is a gastro-intestinal irritant and produces diarrhoea even in small doses. Given intravenously in animals, a 5 per cent. solution produced no fall of blood pressure or other untoward effects. Yatren is readily absorbed from the small intestine and from the rectum; it is excreted in the urine which gives a positive oxyquinoline test, i.e., green colour with ferric chloride. Iodism is never produced though yatren contains 36 per cent of iodine.

Use in amœbic dysentery. Although it can be injected either intravenously or intramuscularly it is generally given by the mouth or as an enema. When given orally it is made up into pills of 4 grains (0.25 gm.) or in cachets containing 8 grains (0.5 gm.). A total of 15 to 22 grains (1.0 to 1.5 gm.) per day can be given. The drug is given daily for a week and repeated for 2 or 3 days during the following two weeks; when given as an enema, a 2 per cent. solution should be used and about 200 c.cm. is given slowly and retained as long as possible. This suffices in acute cases. In resistant cases the drug should be given by the mouth as well as by enema which should be given at night and retained all night if possible.

Muhlens and Menk (1921) were the first to use yatren in 8 resistant cases with remarkable clinical improvement. They gave it by the mouth in the form of keratin-coated pills in doses of 1 gm. three times a day, and supplemented it with rectal injections of 2.5 per cent. solution when ulceration was present. The first course consisted of combined oral and rectal use for 8 to 14 days with sigmoidoscopic controls. A further course of 3 to 7 days was given after a week's interval and later one more if necessary. Birt (1923) tried it in a series of 28 cases of which 16 were believed to be cured. He used enemata of 10 gm. of yatren in 100 c.cm. of water but patients complained of considerable pain. Huppenbauer (1925) claimed that the value of yatren lay in its efficacy in the treatment of chronic amœbiasis and its complications when emetine and emetine-bismuth-iodide had failed. Katsurada (1926) stated that his experience with

yatren had been very satisfactory. He only gave 1.8 gm. daily for 7 days after which the stools became negative. Hirayama (1925) treated 713 cases successfully. Boyers (1925) states that complete eradication of both motile and encysted *E. histolytica* with this drug was problematical. It is however a valuable adjunct in the treatment of this disease. According to Akashi (1926) yatren kills the entamoebæ present in the lumen of the intestine and then gradually attacks those in the superficial layers of the intestinal wall. Emetine, on the other hand, does not act on the amoebæ in the lumen of the gut, but kills the large forms in the intestinal tissues. He therefore recommended that the two drugs should be combined, but considered it advisable to treat acute cases at first with emetine till symptoms abate. Bach and Steinhauer (1926) observed rapid and complete restoration to health with this drug in chronic cases of amoebic dysentery. Dalmeyer (1926) working in Java found yatren unfailingly successful, both in acute and chronic amoebic dysentery. According to Deutsch (1927) yatren is practically a specific against all forms of dysentery in children. Manson-Bahr and Sayer (1927) obtained excellent results.

Yatren has been tried in the Carmichael Hospital for Tropical Diseases, Calcutta, by Megaw, Knowles and others with variable results. Such large doses as have been recommended by the makers and various investigators cannot be given without producing severe diarrhoea. Any dose above 15 to 30 grains (1 to 2 gm.) per day is liable to produce diarrhoea immediately and although there is no tenesmus present, it is troublesome to the patient. Knowles (1928) found that unless diarrhoea is produced the results of treatment appear to be poor. In fact the drug seems to act by producing irritation of the mucous membrane of the gastro-intestinal tract especially of the colon. In a series of 23 cases treated orally yatren gave a ratio of probable cures to failures as 1: 1.3. In 6 intractable cases of chronic dysentery which had combined treatment with yatren by the mouth and per rectum simultaneously, the ratio of probable cures to failures was 1: 1.5.

As may be expected certain cases respond much better to treatment by yatren than others. In chronic cases combined

treatment, *i.e.*, yatren by the mouth and per rectum is advisable. The chief disadvantage of this treatment is the high cost. A standard course of 8 pills orally per day for ten days with a daily rectal injection of 200 c.cm. of 2.5 per cent. solution will cost nearly 20 rupees or approximately 30 shillings. Moreover, this form of treatment is troublesome to the patient and very few can be persuaded to continue with rectal injections for more than a few days. It can only be carried out properly in nursing homes and in large hospitals. Some clinicians have given the drug by intravenous injections but the results have not been superior to those by the other routes. Yatren has also been advised in cases of amœbic hepatitis or even liver abscess, and patients suffering from bacillary dysentery are said to derive benefit from it.

From a perusal of reports of different investigators it is obvious that yatren is worthy of trial in the treatment of chronic cases of amœbic dysentery or carriers, in combination with emetine injections or emetine-bismuth-iodide by the mouth. It has been abundantly demonstrated that both these drugs possess a definitely curative value in amœbiasis, which may be limited when they are used singly. Yatren is readily absorbed but it is possible that it may not reach all the lesions in the bowels in sufficient concentration to kill the parasites. Its action may be intensified when it is combined with emetine by injections. The combination is well tolerated and gives very satisfactory results.

Preparations.

Yatren or sodium iodo-hydroxy-quinoline sulphonate. Dose up to 15 grains (1.0 gm.) daily. *Chardyl* is a Belgian preparation comparable to yatren.

Emetron is a yatren emetine compound which has been introduced for intramuscular injections but is not very effective.

Yarten-casein ampoules for intramuscular and intravenous use have been prepared.

Bismutho-yatren A. & B. have been introduced and tried in the treatment of yaws. The A. compound is the sodium salt of bismuthyl-iodo-oxyquinoline sulphonic acid containing the equivalent of 10 mgm. of bismuth metal per c.cm. The B. compound differs only in being a quinine combination in oily suspension containing 38 mem. of metallic bismuth per c.cm. A. can be used intravenously or intramuscularly, B. intramuscularly only.

Halogenated oxyquinolines. Owing to the relatively non-toxic and supposedly efficient amœbicidal properties of yatren or iodo-oxyquinoline sulphonate, a number of related compounds have been introduced. One of these higher halogenated oxyquinolines, iodo-chloroxyquinoline (vioform, N. N. R.) gives promise of success and is considered better than Chiniofon (N. N. R.) which is sodium iodoxyquinoline sulphonate. This compound is rapidly excreted in the urine in human beings, is non-irritating when given in capsules by the mouth, and no untoward symptoms from its continued administration (250 mgm thrice daily for two days) have occurred in amœbiasis. It appears to be more effective against *E. histolytica* than against other intestinal protozoa.

Anayodin. (Iodoxyquinoline sulphonic acid) has been tried in acute and chronic amœbic dysentery with good results.

ORGANIC ARSENICALS

Stimulated by the success obtained after the oral use of stovarsol (3-acetyl-amino-4-hydroxy-phenyl-arsonic acid or acetarsone, N. N. R.) in syphilis by Fournau (1921), Marchoux (1923) first employed organic arsenicals by the mouth in the treatment of amœbiasis. He found stovarsol to be effective and since then this drug has enjoyed some popularity as an amœbicidal agent. No special chemotherapeutic studies in this connection appear to have been made except that a related compound treparsol (3-formylamino-4-hydroxyphenyl arsonic acid) was tried. Two types of organic arsenicals have been studied in comparison with stovarsol. One series represent carbarsone (4-carbamino-phenyl arsonic acid) and tryparsamide, and the other consists of a series of arsenious trithio compounds represented by arsenious trithio salicylic acid. These compounds are cumulatively toxic but apparently quite active. Of the p-amino-arsonic acid series, the propionamide and the butyramides are not readily available and tryparsamide is not sufficiently effective. Thio-carbamino-phenyl arsonic acid differs from carbarsone only in that an atom of sulphur replaces an atom of oxygen in the carbamino radicle. This replacement makes the compound much less toxic and amœbicidal.

Stovarsol has been used in those cases who had resisted emetine treatment, in doses of 0.25 gm. in pill form twice daily for a period of 10 days. Amœbæ or cysts were found in the stool even after the treatment. Petzetakis (1925) tried the drug exten-

sively and found it an excellent remedy for parasitic infections of the intestinal tract; in infants doses recommended up to one year of age are 0.05 to 0.08 gm. daily; from 1 to 2 years, 0.08 to 0.10 gm.; from 2 to 5 years 0.10 to 0.25 gm. daily. In chronic and relapsing cases of amœbiasis prolonged treatment is necessary and may be supplemented by injections of emetine. He found that the drug can be exhibited over a prolonged period without producing any ill effects. To avoid toxic symptoms, which frequently occur with the drug, the dose should not exceed two tablets (8 gr.) daily for 7 days or 1 tablet (4 gr.) daily for 14 days. Brown (1926) considers that stovarsol is more effective in eradicating amœbæ than emetine. Van Steenis (1927) found stovarsol less effective than emetine or yatren, but very useful against the 'minuta' type of *E. histolytica*.

Knowles (1928) in summing up the literature on stovarsol, says that it is apparent from the large series of papers that on the whole the results are not too bad. Almost every writer comments on the drug as one easy to administer and well-tolerated by the patient. On the other hand it has less powerful amœbicidal action than emetine, and some authors comment on its toxic effects. Occurrence of a measles-like rash was not uncommonly met with and cases of acute exfoliative dermatitis have been recorded after administration of stovarsol. Knowles treated 32 patients, mostly chronic, in Calcutta; the ratio of probable cures to failures in these was 1: 1.1. He is of opinion that stovarsol has a definite place in the treatment of chronic intestinal amœbiasis. The ease and simplicity of the treatment are remarkable. The usual course is one tablet of 4 grains each night and morning for ten days. No toxic symptoms were observed, while the drug undoubtedly has a hæmatinic value. The patients taking stovarsol are not the miserable and unhappy beings like those on emetine or emetine-bismuth-iodide treatment. The average cost of treatment is 2 to 3 rupees. It is particularly useful in chronic type of cases and the chances of eradication of the infection are 40 to 50 per cent. The drug was used by Knowles as an after-treatment, the relief of clinical symptoms being first obtained with emetine injections and bismuth treatment. The patient was then given a few days' rest

and a ten-day-course of stovarsol afterwards. This usually leads to rapid improvement in general health and the infection may be eradicated. For chronic carriers stovarsol may be followed by a course of emetine-bismuth-iodide.

Carbarsone. This compound 4-carbamino-phenyl arsenic acid was first prepared by Ehrlich in 1909 and is a white crystalline powder, stable in air, without odour or taste. It contains 28.85 per cent. of arsenic when anhydrous. It is practically insoluble in water but dissolves in alkaline aqueous solution, and it melts at 174°C. Carbarsone has been put on the market by Eli Lilly & Co., of Indianapolis, U.S.A., and is available in capsules of 0.25 gm. each; recently the drug has also been manufactured by an Indian concern. Carbarsone is absorbed on oral administration at the same rate as stovarsol (acetarsone). It is less toxic but has much more powerful amoebicidal properties, its therapeutic index being eight times as favourable as stovarsol. In amoebic dysentery the drug is administered by the mouth in a hard gelatine capsule in doses of 0.25 gm. twice daily for ten days so that a total of 5 gm. is given. For children and weakly individuals the total dosage is smaller. The average total dose based on body weight is about 75 mgm. per kilogram given in ten days. This dose is a relatively safe one to employ and calculation should be made on this basis of the approximate total amount to be given in one course of treatment. No toxic effects are produced even in person who has some liver injury. The largest dose given without producing any toxic effect was 204 mgm. per kilo. during six weeks. Out of a series of 40 cases treated, all were freed from *E. histolytica* in the stool and remained free for one month after treatment. Concurrent protozoal infection was present in many of these patients. *E. nana* were eradicated in a number of cases, so also were *Chilomastix* and *Iodamoeba butschlii*. *Trichomonas* infection responded favourably to carbarsone therapy in two patients. In cases infested with *Dientamoeba fragilis* and *E. coli* the symptoms subsided. Chopra and his co-workers (1933) tried carbarsone in a number of cases of chronic amoebic dysentery with vegetative and cystic amoeba in the stool; 0.25 gm. of the drug was given twice daily for

10 days, the criterion of cure being six negative examinations during a fortnight following the treatment. In a series of 31 cases a ten-day course cured 74.2 per cent. of cases, 12.9 per cent. remained indeterminate and a similar percentage uncured. The proportion of probable cures to failures in this series was 5.75 : 1, as compared with 3.5 : 1 obtained by Knowles in a similar series with emetine bismuth iodide, and 3.16 : 1 obtained by Acton and Chopra with kurchi-bismuth-iodide.

Toxic effects. On laboratory animals no untoward symptoms have been noted following its continued administration within therapeutic range. With doses approaching the M.L.D. by the mouth (150 mgm. per kilo. in guineapigs, 200 mgm. per kilo. in rabbits and from 200 to 250 mgm. per kilo. in cats), the animal may present symptoms of lethargy, loss of weight, abdominal distension, diarrhoea, sluggish reflexes, and failure of the pupil to response to light. Histological examination of animals dying from such doses revealed some renal necrosis and tubular degeneration. On repeated oral administration of doses within therapeutic range (50 mgm. per kilo. daily for ten days in monkeys) no toxic symptoms were observed and in rabbits after 30 mgm. per kilo. daily for ten days no evidence of tissue injury was found.

Cautions and contraindications. Since it contains a substituted amino group in para position to the arsenic atom, it must be used with caution till it is established that it does not act on the optic nerve. As with arsenicals generally, it is contra-indicated in the presence of kidney or liver disease; it should not be used in amoebic hepatitis.

Compounds of mercury. The antiseptic action of mercury compounds is well-known and many of them have been tested *in vitro* in the hope of getting a compound which is more parasitotropic and less organotropic, but none of them have been found effective in amoebic dysentery.

Mercurochrome 220 has been tried in the treatment of amoebiasis. For detailed description see the section on mercury.

Kaolin, also known as 'bolus alba', is a native hydrated aluminium silicate purified from sandy matter by elutriation. Extensive deposits are found in China. It occurs as smooth white or yellowish white powder or in lumps, insoluble in water, in cold dilute acids, and alkaline hydroxides. It is a powerful adsorbant and has an earthy clay-like taste and odour when moistened. Internally it is used in doses of 3/4 to 1 ounce (8 to 30 gm.) with water, milk or gum acacia emulsion. It is best given on an empty stomach. Kaolin and talc (a purified native hydrous magnesium silicate) have been given as a substitute for bismuth in gastro-intestinal affections; both are insoluble and unaffected by acids. Kaolin along with charcoal, talc, kieselguhr, etc., has a remarkable power of adsorbing toxins and antitoxins. Diphtheria toxins and antitoxins are adsorbed by animal charcoal but not by kaolin, talc, kiesel-

guhr or wood charcoal. Tetanus toxin is adsorbed by all the above agents. In general gram-positive bacteria are adsorbed much more readily than the gram-negative. Colloidal kaolin has been tried intravenously in septicæmic conditions, but it has a direct hæmolytic action on the blood; it also tends to produce allergic shock.

On account of its adsorbing power kaolin has been given by the mouth in the treatment of acute bacillary and amoebic dysentery in doses of 20 to 30 gm. stirred in water after a preliminary cleansing of the bowels with calomel. It is particularly useful in cases where a large number of stools have been passed and symptoms of toxæmia are present. It is undoubtedly useful in chronic cases. Asiatic cholera has been treated by kaolin, 400 to 800 gm. being dissolved in a litre of water; three ounces or a wineglassful of this suspension is given every half hour till symptoms abate, then every hour or every two hours up to 12 to 15 hours. In a series of 41 cases similarly treated with kaolin 1 death occurred, while of 24 treated with hypertonic saline 7 died. It is said to have the property of absorbing bacterial toxins and improving the general condition of the patient. Rectal injections of the same suspension have also been recommended in this disease. The action appears to be entirely mechanical. It is also useful in diphtheria, ptomaine poisoning, bacillary diarrhœa, etc.

Osmo-kaolin or colloidal kaolin also has been tried. A commercial variety of this is called *collasan*. The dose should be a teaspoonful or more in water, two or three times a day, combined with an aperient if necessary. Colloidal kaolin should contain no organic or inorganic matter and should give no growth of bacteria either aerobically or anaerobically. This preparation is a very efficient absorbent of bacteria and toxins and has been used with advantage in chronic intestinal disorders and for healing ulcerations of the mucous membranes. A useful prescription is, osmo-kaolin 3½ ounce, tragacanth mucilage 1 ounce, peppermint oil 10 minims, water 8½ ounces. A wineglassful of this is given every 6 hours. Osmo-kaolin has also been tried in amoebic and bacillary dysentery as well as in rheumatism and gout. It can be substituted for bismuth carbonate in the combined treatment with emetine and bismuth.

Kaylene is described as activated colloidal aluminium silicate. It absorbs toxins and is said to act as an intestinal antiseptic. It has been recommended in chronic dysentery, diarrhœa and also for Asiatic cholera.

Sil-Al. Dose 1 drachm (4.0 gm.) in water, half an hour before meals, is used for the same purpose as kaolin.

Rivanol (2-ethoxy-6: 9-diamino acridine lactate) was originally prepared as an antiseptic. A 1 in 1,000 solution kills *E. histolytica* in cultures in 20 to 24 hours. Experiments on cats infected with *E. histolytica* did not prove definitely its curative effect when given per rectum. It produced spasmodic contractions of the smooth muscle of the gut very similar to those produced by papaverine.

Peter (1928) gives a lengthy account and discussion of its use in the treatment of a small series of cases of dysentery in adults, children and infants, clinically and microscopically amœbic in origin. A 1 in 10,000 solution used as rectal enemas, 3 to 6 times daily for 3 to 4 days, cause the disappearance of amœbæ and cysts; spasmodic contractions of the colon however occurred. In order to receive rivanol treatment, ambulatory patients must be put to bed for at least half the day. Tenesmus is controlled by tincture of opium. A preliminary cleansing non-irritating enema is given. In adults 1 in 2,000 solution of rivanol in distilled water is the best; 500 to 800 c.cm. of this solution at body temperature are given per rectum, the patient lying on his back or side. If ulceration of the cæcum or ascending colon is present, the knee-elbow position is the best. The injection must be retained as long as possible, at least 15 minutes. In every case there was rapid amelioration of clinical symptoms, the temperature came to normal, pain and tenesmus disappeared and stools became normal. In two to three days following this treatment, vegetative and encysted forms of amœbæ are said to have disappeared from the stools. It is claimed to be directly amœbicidal, having in addition a sedative and anæsthetic action on the inflamed and irritated gut.

Rivanol has also been given by the mouth both in amœbic dysentery and non-specific mucous colitis. After a saline purgative, 0.05 gm. of rivanol is given 3 times a day for 4 to 8 days, up to a total of 0.9 to 1.7 gm. Cure of amœbic dysentery is said to have been obtained but the results have not been confirmed.

Di-Hydranol. (2-4 dihydroxyl-phenyl-n-hepatone), is given in doses of 0.3 gm. in capsules 2 or 3 times a day for seven days in amœbic dysentery, a total of 14 to 10 gm. being required. It is believed to have a specific effect on *E. histolytica*.

Heptyl resorcinol. Faust (1930) offered evidence that heptyl resorcinol is very successful clinically in amœbiasis. Of the many compounds only hexyl, heptyl and octyl resorcinol are available. The toxicity of these compounds on oral administration appears to increase with the increase in size of the alkyl radicle. Octyl resorcinol may be definitely ruled out because of its local irritating effects. In natural *Balantidium coli* infestations in guinea-pigs heptyl resorcinol was found to be definitely curative, but in doses approaching the M. L. D. hexyl resorcinol is less toxic than heptyl, has a stronger antiseptic action and is worthy of trial.

CHAPTER VIII

PALLIATIVE REMEDIES IN AMŒBIASIS

As a considerable residuum of cases of amoebic dysentery is left uncured, Henry and Brown (1924) examined a number of reputed remedies against this disease.

Monsonia ovata and *Rhyncosia adenodes* are used in South Africa, *Brucea abyssinica* and *Brucea sumatrana* are used in Abyssinia and Malaya respectively. These four drugs have been examined chemically without showing any active constituent to which their amoebicidal action could be attributed. *M. ovata* is another of these remedies and a substance called *entericin* was isolated from it, but entericin is an ill-defined substance. From the two species of *Brucea* mentioned above, amorphous hitters have been isolated, but trials on free-living protozoa show them to be quite inactive either alone or in the presence of alkali.

The bark of *R. adenodes* was examined by Henry and Brown, but no active substance other than tannins was found. These investigators tried to combine biological and chemical methods with the hope of selecting from the large number of such available drugs any which seemed promising enough for detailed examination. The finely ground drug was exhausted with boiling alcohol and the extract concentrated *in vacuo*; the thick syrup thus obtained was diluted with water to precipitate resinous and fatty matter and this gave preparation A. The liquor was further concentrated *in vacuo* to remove all alcohol, and this was B. This was treated with lead acetate to remove all tannins and this preparation was C and the residue after recovering the precipitate and removing excess of lead was D.

The strength of this final product was adjusted so that 1 c.cm. represented a certain quantity of the drug. All four portions were then tested on glaucoma, an actively motile ciliate occurring in hay infusions. A and D proved non-toxic to this organism and B and C were toxic. The activity was found to be due to one of the components of C and on testing it was found to be the tannin fraction.

It is interesting to note that the action of many of the drugs used against non-specified dysenteries in India and elsewhere is due to their astringent effects and not to the toxic effects of any of their constituents, on the parasites. The chemistry of tannins is still not very advanced. Only a few tannins are obtained in pure condition, e.g., gallotannin (from galls) which can be obtained commercially in crystalline form; ellagic acid, chebulinic acid (from myrobalans), catechin (from Gambier catechu) can also be obtained in more or less pure form. Some of the tannins are readily soluble in cold water and these are in most cases toxic to glaucoma; other soluble in boiling water are non-toxic. The crystalline and sparingly soluble tannins have little or no action on glaucoma. The toxicity to tannins appears to be the inherent property of these compounds, but their action is not very powerful. They kill glaucoma in dilutions of 1 in 1,000 to 1 in 2,000, while the alkaloid conessine from *H. antidyenterica* kills in 1 in 120,000 or more. In view of these facts it appears to be unlikely that any of these tannins or the vegetable drugs which contain them will prove to be of any great utility in resistant forms of amoebiasis.

PLANTAGO OVATA

This is known in the vernacular as *Ispaghula* or *Isabgul*. It is a Persian herb which also grows in the Punjab, Sind and the United Provinces. The seeds which are commonly used are imported from Persia into Bombay in large quantities. In the Tibbi books the seeds are found described under the name of *Bari-i-kaluna*. They are boat-shaped and generally pinkish grey, but the colour may vary, some being brown while others are nearly white with a pinkish tinge, the latter are preferred. *Isabgul* is a well-known and popular remedy in chronic dysentery in India. So commonly is it used in this condition even by Western practitioners that it has found its way into the British Pharmacopœia. When steeped in water the seeds swell up giving out large quantities of a sticky, bland mucilaginous substance with no taste or odour. The seeds of several other species of the same genus exhibit similar properties; *Plantago amplexicaulis* grows in many parts of India and furnishes the brown variety of seed; *P. major* (Luhuriya) grows in the Himalayas; other species of plantago are *P. psyllium* (which is practically the same as *P. major*), *P. brachyphylla* and *P. lanceolata*.

The pericarp which contains all the mucilaginous matter is removed from the seed and is sometimes prescribed instead of the whole seeds by indigenous practitioners. When the seeds are roasted they are said to have a more astringent effect.

Chemical composition. The seeds were examined by Henry and Brown (1923). The chief constituent is the mucilage which is con-

tained in the cells of the epidermis. After excluding the mucilage they could find no active principles toxic to protozoa except tannins. The author found a glucoside named *aucubin* in small quantities.

Pharmacological action. The jelly-like substance occurring in the seeds is acted on by the digestive enzymes to a very slight extent and therefore most of it passes through the small intestine unchanged. It is also not acted on by the intestinal bacteria such as *B. coli*, *B. shiga*, *B. flexner*. The seeds coat the surface of the ulcer and also adsorb the toxins present in the gut.

Therapeutic uses. The seeds on account of their emollient and demulcent effects, are commonly used in India as a remedy in chronic diarrhoea and dysentery. They are thoroughly cleaned from sand and grit with which they are always mixed. Two to 4 heaped dessertspoonfuls prepared in one of the following ways may be taken : (1) With a little sugar and shaken up in a cupful of water. (2) The seeds are mixed with water and allowed to stand for 15 to 20 minutes till all the mucilage comes out. The swollen mass is then swallowed. (3) A mucilaginous decoction made by boiling one to two tablespoonfuls of the seeds in 2 pints of water till the volume is reduced to half. This is given in divided doses, and is preferred especially in acute dysentery.

The first method is preferable as it allows the seeds to mix with the intestinal contents thoroughly so that they spread over the whole of the surface of the mucous membrane evenly; whereas if the mucilage is allowed to form before administration it forms a sticky mass which is not evenly distributed and much of the demulcent action is lost. The drug has no amoebicidal effects and its action appears to be entirely mechanical. The irritated or ulcerated surfaces of the intestinal mucosa are soothed by the demulcent action of the mucilage, which is not acted on by the intestinal juices. It covers the surface of these ulcers and in this way protects them from further irritation. The drug is tasteless and is equally suitable for children and adults.

There is little literature on the use of this drug in dysentery, but it has been unanimously acclaimed as having a remarkably beneficial action in chronic dysentery. The author has given extensive trials to the seeds in chronic diarrhoea and dysentery with excellent results and strongly recommends this drug in chronic irritative diarrhoea and dysentery of both amoebic and bacillary origin. In chronic spastic constipation the drug produces a laxative action. It should be remembered, however, that unless sufficiently large quantities of the seeds are taken no action is produced. One or two heaped tablespoonfuls may be given at a time once or twice daily. It has a laxative action similar to agar.

A number of proprietary preparations composed of the mucilage containing principle of the seeds have been recently put on the market.

AEGLE MARMELOS

It is commonly known as 'bæl' tree and has many vernacular names, *Billwaphal* or *Sripthal* in Sanskrit, *Bæl* in Hindi and Bengali.

The tree is indigenous and is cultivated all over India. In Hindu medicine the root bark is used in the form of a decoction as a remedy in hypochondriasis, melancholia, intermittent fever and palpitation of the heart. The leaves are made into a poultice and applied to the inflamed parts. The medicinal properties of the fruit have long been known to Hindu physicians. Two kinds of the fruit are found in the bazar—a small and wild variety, and a large cultivated variety. The full grown fruit of either variety, when it just begins to ripen, is best for medicinal purposes. It is used in two forms.—

(1) *The unripe or half-ripe fruit.* This is regarded as an astringent, digestive, and stomachic and is an excellent remedy in irritation of the alimentary canal owing to the presence of tannins or mucilaginous substances. It is sometimes used in combination with opium by Ayurvedic practitioners.

(2) *The ripe fruit.* This is sweet and is considered as aromatic and laxative. The dried pulp is pale yellow or flesh-coloured and when mixed with water yields a pleasant orange coloured 'sherbet' which has slightly laxative properties.

Both unripe and ripe fruits contain tannin in small quantities. The dry pulp moistened with cold water yields a red liquid chiefly containing mucilage and probably 'pectin', which separates if the liquid is concentrated by evaporation. As far as is known the principal constituent of bæl fruit is mucilage. Henry and Brown (1923) found only small quantities of tannins present in the ripe fruit, some of which were toxic to glaucoma. More recently Dutt & Dikshit (1930) found in the pulp, besides the usual constituents, a body known as *marmelosin*.

Therapeutic uses. The fruit is said to have an astringent action and this property is not lost by drying, although fresh fruit is preferable. It is said to possess a remarkable efficacy against chronic dysentery and diarrhoea; so commonly was it used by Western practitioners in India in old days that it was included in the British Pharmacopoeia in the middle of last century. It was believed to be an invaluable remedy in obstinate cases of chronic diarrhoea and dysentery unattended with fever, and was given in the form of a powder or as a confection. There is very little literature available regarding the effects of 'bæl' in amoebic dysentery. During recent years the drug has not been tried on a large scale and controlled by proper examination of stools. It has little or no effect in acute dysentery, though the powder is said by some to produce good effects in this condition. The first noticeable effect is that blood rapidly disap-

pears and the stools assume a more fæculent form. Fresh fruit is considered by some to be more efficacious than dried fruit. The main action of the drug in chronic dysentery is due to its demulcent properties and also to a certain extent to the tannins present in it. The drug is worthy of trial in chronic amœbiasis where other remedies have failed.

Preparations.

(1) **Extract of bæf.** This is made from fresh unripe fruit. Dose $\frac{1}{2}$ to 1 drachm 2 to 3 times a day.

(2) **Liquid extract of bæf.** This is prepared from dried slices of unripe fruit. Dose $\frac{1}{2}$ to 1 drachm several times a day. It is said to be much less effective than the fresh extract.

(3) **The powdered dried pulp.** This is said to keep well in air-tight bottles. Dose $\frac{1}{2}$ to 2 drachms in chronic dysentery.

Decoction of the dried bæf fruit and syrup made with fresh or dried fruit are also used.

ACORUS CALAMUS

It is commonly known as 'sweet flag', in English, 'Bach' in Hindi and Bengali. It is a semi-aquatic perennial herb with an indefinitely branched rhizome. It is really a native of Europe and North America, but is cultivated in damp marshy places in India at an altitude of 3,000 to 6,000 feet; it has established itself on the edges of lakes and streams. The long creeping horizontal rhizome is collected in the autumn, cut into pieces and dried.

Chemical composition. The dried rhizome yields 1.5 to 3.5 per cent. of a neutral yellow aromatic essential oil having an agreeable odour. The chief constituent of this oil is asaryl aldehyde. There is also a bitter glucoside named acorin and certain other substances, such as eugenol, asarone, pinene and camphene are present. The drug contains abundance of starch and a little tannin. Henry and Brown (1923) found an essential oil which was toxic to glaucoma but no other active principle except tannins.

Therapeutic uses. The rhizome is emetic, nauseant, anti-spasmodic and carminative. In doses of 35 to 40 grains it produces a violent and persistent emesis; it has an expectorant action and is used as a remedy for asthma. The drug is a very old remedy for chronic diarrhœa and forms part of a number of mixtures in the Hindu medicine. Evers (1875) tried it in chronic dysentery with good results. It has been discarded in recent years, and any effect it produces is due to the presence of tannins.

HELICTERES ISORA

It is commonly known as the East Indian screw tree belonging to the Sterculiaceæ family. In Hindi it is known as *Marar* or *Mararphall* (or the pod used in dysentery), in Gujrati it is known as *Mriga shingha* or deer's horn. It is a tall shrub, or a small tree resembling the common hazel. It has bright red and showy flowers which appear in the rainy season. The plant grows in Western India and in Kashmir. According to Ainslie it is used by Hindu physicians as a remedy for offensive sores inside the ear. It also forms part of prescriptions used for the cure of griping in the bowels and flatulence especially in children. The pods have demulcent and slightly astringent properties.

Chemical composition. The author analysed the pods, but no active principles with the exception of tannins and the demulcent substances could be discovered.

Therapeutic uses. The pods are used in some parts of India in the treatment of chronic dysentery. In some patients the symptoms are considerably ameliorated.

CASTELA NICHOLSONI

This plant is known as *Chaparo amargosa* in Mexico and was used by Mexicans in the treatment of dysentery. It is a semi-rubiacceous plant and its active principle is a glucoside called *castelin* and a bitter principle called *castelamarin*. Castelin crystallizes in long white needles and dissolves in 85 parts of water and is also soluble in alcohol. It is dextro-rotatory and is readily hydrolysed by dilute acids, yielding *castelagenin*.

Pharmacological action. Schneider (1925) found castelin, and castelagenin to be toxic, death being produced in animals from gradual paralysis, the respirations ceasing before the heart. Under the microscope 1 in 10,000 of the detannated fluid extract caused loss of movements of *E. histolytica* and the assumption of a spherical form. These observations have not been confirmed by other workers.

The 'chaparo' (any part of the plant, root, leaves, bark), is powdered and measured in heaped teaspoonfuls. Five teaspoonfuls are given daily, i.e., three as drinks, each prepared by boiling a teaspoonful of the powder in 8 oz. (240 c.cm.) of water for a quarter of an hour and two for enemata similarly prepared with 12 oz. (360 c.cm.) of water. The decoction is cooled and strained before administration. The enema is given by a long rubber catheter, passed as high as possible, with the patient in the knee-elbow position. The drinks are given half an hour before breakfast, lunch, dinner and supper and enemata at 10 a.m. and 6 p.m. The treatment is continued for 10 consecutive days. The decoction has a very bitter taste. Some cases, apparently incurable with emetiae, appear to have been benefited by 'chaparo'.

SIMARUBA BARK

Simaruba bark is obtained from various species of Simaruba, *S. officinalis*, *S. amara*, *S. glauca*, etc. It was brought to Paris in 1713 from Guiana, where it was said to have been used with success by the natives in the treatment of dysentery. It soon gained a reputation in Europe and was imported in large quantities. The active principle of the bark is a crystalline bitter substance possessing neither alkaloidal nor glucosidal properties. It has been used in amoebic dysentery with some success in a similar manner as 'chaparo', a handful of bark being cut up and a decoction prepared in the same way. It does not produce any marked therapeutic effects in this disease and is now seldom employed.

Uzara is another African plant belonging to the N. O. Asclepiadaceae. It is a proprietary article recommended by certain German workers, but is of doubtful efficacy.

CHAPTER IX

DRUGS USED AGAINST FLAGELLATE DIARRHŒA

These may also be considered here. There has been a considerable amount of difference of opinion regarding the pathogenicity of intestinal flagellates present in the human gut. Although they are undoubtedly present in large numbers in irregular diarrhœa especially in children, it is doubtful if they are the causal organisms. The two flagellates most frequently met with are *Giardia intestinalis* and *Trichomonas hominis*, the former being believed to be pathogenic. The organisms are not always limited to the intestinal canal and *Lambli*a (*giardia*), *intestinalis* has been found in the gall bladder and bile ducts, liver abscesses, pleural exudates, etc. In children they produce intermittent diarrhœa infection being carried through cysts and the house fly. As proof of their pathogenicity it has been pointed out that in *Lambli*a infections the stools are often pale and pultaceous, having a characteristic odour; most of the cases show eosinophilia, which disappears after treatment. Inoculation in cats per rectum or feeding them with *Giardia intestinalis* and murtis produces severe diarrhœa which may be fatal. Autopsy shows inflammatory and necrotic changes in the bowels containing active stages of the flagellates throughout.

Chilomastix mesnili, another human flagellate, may cause diarrhœa although it has been considered harmless. Various trichomonas have been found in the intestines, biliary passages, mouth, vagina and bladder.

Treatment. The course of these diarrhœas is irregular and it is very difficult to say whether a drug has caused disappearance of the flagellates or not. Many drugs have been tried in these cases. Essence of turpentine is beneficial, but the results may be temporary. Carbonate of bismuth in doses of 30 to 90 grains daily for one or two months has been suggested. The drug is stopped every 10 days, and bile and calomel are given in the interval to stir up the lurking parasites. Bismuth salicylate in doses of 10 grains 3 times a day has been recommended, several courses of one week or 10 days being given during a period of six months. Arsenical preparations such as arsphenamin and neoarsphenamin, in the usual doses intravenously, can be tried; it is better to give a desensitising dose of 0.2 gm. first. Stovarsol is given in doses of 0.5 to 0.75 gm. daily on the first three days and 1.0 gm. daily for next three or four days, the course being repeated with four-day intervals between each up to three weeks. Treparsol in the usual doses has been reported to be a specific in giardia and trichomonas diarrhœa. Carbarsone in 0.25 gram doses 2 or 3 times a day

for 10 days has been recommended. Thymol in form of enemata (1 in 2,000 solution) and orally in doses of 0.25 to 0.5 gm. has been tried. Yatren and carbon tetrachloride in 20 minim doses in children and 5 c.cm. doses in adults, followed by magnesium sulphate, gave temporary beneficial effects. Disappearance of both trichomonas and Giardia on pure meat diet has been observed when the condition is associated with faulty carbohydrate digestion.

SECTION II

REMEDIES USED AGAINST LEISHMANIASIS AND TRYPANOSOMIASIS

REMEDIES USED IN LEISHMANIASIS

Since the discovery of the causal organism of kala-azar by Leishman and Donovan in 1903 our knowledge of this species and the genus leishmania has rapidly increased. At the present time at least three distinct species are known to occur in man, viz., *L. donovani*, *L. tropica* and *L. braziliensis*. *L. donovani* is the cause of kala-azar or visceral leishmaniasis as found in parts of India, China and the Mediterranean littoral. There are also a few small areas where the disease has been found in Turkestan, the Sudan, etc. *L. tropica* (Wright) causes the cutaneous infection known as 'Oriental sore,' Delhi-, Lahore-, Frontier- or Bagdad sore, Aleppo boil. *L. braziliensis* is the cause of American cutaneous leishmaniasis, which causes secondary ulceration of the muco-cutaneous areas of the nose and mouth.

Still another manifestation of cutaneous leishmaniasis due to the species *L. donovani* is found in India as a sequel to kala-azar. This condition occurs in anything up to 5 per cent. of cases of kala-azar. A certain number of patients presenting themselves for treatment of this condition deny any previous history of kala-azar; many give a history of fever of a long-continued nature, with enlargement of the spleen. As a certain number of cases of kala-azar are known to recover without treatment, the probable assumption is that these cases are the sequel of a transitory attack of kala-azar when the patients' natural resistance has brought about a cure of the generalised disease.

As found in man and other vertebrate hosts, the parasite is a minute oval protozoon about 3μ by 2μ . They are found in the endothelial cells of the vascular and lymphoid tissues, in

the liver, spleen and bone marrow. In culture and in arthropod hosts the organism develops into a flagellated form.

Recent work in India has incriminated the sandfly *Phlebotomus argentipes* as a vector of *L. donovani*. Much evidence has also been accumulated which incriminates the sandfly *P. papatasi* as the vector of *L. tropica*, and it is very probable that other species of the genus *Phlebotomus* will be found to be vectors of leishmaniasis in other parts of the world.

That a certain amount of immunological resistance is developed after an attack is well known. The number of instances in which a second attack of kala-azar has occurred is negligible and it is a well-known fact that once a person suffers with oriental sore he is most probably protected for life.

Visceral leishmaniasis or kala-azar is a terrible scourge in India and has been responsible for a very high mortality. Without treatment the prognosis is usually death within two years. The use of antimony, especially the pentavalent compounds, in kala-azar constitutes one of the most important advances in chemotherapy and has revolutionised the treatment of the disease. To produce its curative effect antimony must penetrate the endothelial cells in which these organisms are living.

CHAPTER X

ANTIMONY AND ITS DERIVATIVES

Antimony has a very interesting history. Grey antimony has been used from the earliest times in the East as an 'eye salve' for protection against endemic eye diseases and as a remedy for oriental sore. In the 16th and the 17th centuries antimony was considered as a panacea for many diseases, *c.g.*, syphilis, leprosy, plague, cancer, ague, perhaps a forecast of its most recent use in chemotherapy. As early as 1631 the preparation, antimony tartrate or *larlar emetic* came into existence and by the end of the 17th century more than a hundred preparations of antimony were in use in medicine, chiefly against plague and other infectious fevers. Owing, however, to its indiscriminate use many deaths occurred and it was discarded to a great extent, and in many places its use was actually prohibited. During the last two decades antimony compounds have proved very useful in the treatment of some of the tropical diseases of parasitic origin, such as trypanosomiasis, leishmaniasis, bilharziasis, etc. The compounds largely used till lately were the double tartrates of potassium and sodium, for the obvious reason that being double salts they are not readily dissociated, and therefore have not such marked irritant or corrosive properties as the inorganic salts. They, however, suffer from certain disadvantages, one of the chief being that small doses, a maximum of $2\frac{1}{2}$ grains, can only be given at a time, and the treatment is very protracted in such diseases as trypanosomiasis, where a high concentration of antimony in the body, maintained for a long time is necessary to produce the desired therapeutic effects. Subcutaneous and intramuscular injections of these compounds are extremely painful, and even when administered in oil, are very unsatisfactory. Intravenous administration, which is a more difficult procedure, is the only method by which they can be given. It is for this reason that efforts have been directed

towards preparing such compounds as can be administered readily in fairly large doses, without producing untoward effects, so that the therapeutic effects are rapidly attained.

Pharmacological Action

The action of the antimony ion in the main resembles that of the arsenic ion, the chief differences lying in its stronger local irritant effects and more difficult absorption.

Action on protozoa. The salts of antimony, arsenic and bismuth have been shown to have special affinity for certain pathogenic protozoa. Antimony destroys trypanosomes in drawn blood in such high dilutions as 1 in 500,000. The non-pathogenic protozoa such as the paramoecium are not affected even by concentrations of 1 in 5,000. It would appear therefore that these compounds have a true specific effect against pathogenic protozoa in the same way as quinine has against the malarial parasites. Antimony compounds are effective against a variety of protozoal infections met with in the tropics.

Externally. When rubbed into the skin, antimony salts produce a characteristic inflammation, at first papular then vesicular and lastly pustular, the rash looks like the eruptions of smallpox. Given subcutaneously, the salts give rise to severe pain and inflammation, often followed by suppuration and sloughing. Salts such as the chloride act as powerful escharotics.

Internally. When given by the mouth tartar emetic has an acrid metallic taste and in very small quantities it produces no symptoms except perspiration. The stomach experiences a slight sensation of soreness, a sensation easily mistaken for hunger. In somewhat larger doses it produces increased secretion of mucus from the stomach and the intestines. Diarrhoea with colic is produced, numerous liquid motions being passed. The secretion of the bronchial mucous membrane is increased and the secretion of most mucous membranes is enhanced. Large doses (2 to 3 grains) give rise to nausea and vomiting accompanied by marked depression and the usual accompaniments of emesis, *e.g.*, salivation, profuse perspiration, acceleration of the pulse, etc. All these symptoms are produced reflexly through the medulla. As an emetic the action of tartaremetic is somewhat tardy taking 8 to 20 minutes and sometimes half an hour; hence in cases of poisoning it is unsuitable as an emetic and is never used. The emesis is produced by the direct irritant action of the drug on the stomach.

Absorption and distribution. In the stomach, antimony is slowly dissociated and produces irritation, hyperaemia and swelling of the mucosa. The acid reaction of the gastric juice probably facilitates this process; dissociation also occurs in the intestines

where the reaction is neutral or alkaline. As a rule vomiting removes the compound from the stomach and very little passes into the intestines, but when it does it produces diarrhoea and colic. Absorption of antimony is very slow from the skin or from the gastro-intestinal tract. As it is too irritating to be administered by subcutaneous or intramuscular routes, the intravenous route is the only possible one. Fortunately the toxicity of these compounds when given by this route is very low, as large amounts are rapidly excreted by the kidneys. From the blood, antimony passes into the tissues much more slowly than arsenic. It is found in considerable quantities in the liver and the spleen especially if administered in metallic form. The volume of both the liver and the spleen is considerably increased after intravenous injections and the automatic movements of the latter organ are stimulated.

Circulation. The cardio-vascular effects produced by antimony resemble those produced by arsenic, but acceleration of the pulse seen after tartar emetic is a reflex effect due to the emetic action and not to the absorption of the antimony ions. When injected into a vein, antimony acts directly on the cardiac muscle and capillaries, producing a slow and weak pulse; the heart muscle is depressed, the capillaries are dilated. There is paralysis of the walls of the arterioles due to its direct action on the muscular coat; the vessels of the splanchnic area are particularly affected. The blood pressure falls on account of vaso-motor paralysis; tachycardia may occur and may be distressing. The heart becomes weak and rapid at first, and is later slowed, the contractility of the cardiac muscle is eventually destroyed and the heart stops in diastole.

It is possible that dissociation of antimony compounds occurs in the blood and the antimony ions combine with the proteins of the plasma. The alkalinity of the blood and the number of erythrocytes are said to decrease while the leucocytes are said to be increased.

Tartar emetic and organic antimony compounds do not hemolyse or agglutinate erythrocytes either *in vitro* or *in vivo*. Concentrations as high as 1 in 20 have no effect on either washed or unwashed corpuscles, and intravenous injections of 0.02 gm. per kilo. produce no intravascular agglutination.

Respiration. There is slight initial acceleration but soon there is nausea and the respiration becomes shallow and irregular. In cases of poisoning, respiration is very slow, laboured and finally ceases along with the stoppage of the heart. Intravenous injections stimulate the respiration slightly; large doses produce marked congestion and oedema of the lungs, in fatal cases of poisoning.

Secretions. The secretions such as perspiration, saliva, mucus, sputum, bile, etc., are increased. The increase of saliva and perspiration are generally reflex being secondary to nausea, although a part of

the increased activity of salivary and other glands may be due to the direct stimulating action of the antimony ions eliminated in them. The quantity of urine is increased with small doses; with large doses it is decreased and may even be suppressed.

Metabolism and temperature. The effects of antimony on metabolism have not been studied so thoroughly as those of arsenic, but antimony compounds seem to present a strong resemblance to the arsenicals. The non-protein nitrogen of the blood is said to be increased in some cases after intravenous injections, and very small quantities given repeatedly by the mouth are said to increase the glycogen and fat content of the liver without apparently altering the rate of excretion of nitrogen in the urine. Prolonged use of toxic doses produces fatty degeneration of many organs, probably owing to diminished oxygenation and metabolism.

Antimony salts have a distinct antipyretic effect. Vomiting is also accompanied by a fall of temperature which may amount to 1°C. (1.5° to 2°F.). During the collapse stage the temperature may fall much below normal because of the slowing of the heart, dilatation of peripheral capillaries and increased perspiration.

Central nervous system. In the frog, subcutaneous injections of the double tartrates produce initial stimulation of the medulla followed by paralysis; later, the spinal cord and the motor ganglia of the brain become paralysed and the reflexes are lost. In mammals, its effects are more obscure. The animals generally die of convulsions, from respiratory and cardiac failure, but it is difficult to say whether these are due to the action of the drug on the central nervous system or due to vascular paralysis or severe gastro-intestinal irritation. It undoubtedly has a depressing effect on the nerve cells even in moderate doses. In cases of poisoning with antimony salts, there is motor and sensory paralysis and loss of reflexes, the latter effect being due to its action on the cord.

Excretion. Antimony salts are mainly excreted by the stomach, the intestines and the kidneys; traces occur in the bile, the sweat and in the milk, and possibly also in the bronchial secretion. There is less danger of cumulative poisoning than with arsenic since antimony is more rapidly excreted. After intravenous injection of 0.12 gm. of tartar emetic, 30 per cent. of antimony is excreted in the urine in 48 hours; of 1.7 gm. injected in a six weeks' course, 1.0 gm. was recovered from the urine. No data are available as regards the quantity excreted by the faeces. It should be used with caution in diseased conditions of the kidneys, the alimentary, the circulatory and the respiratory tracts, especially the former. Large doses produce inflammation of the kidneys accompanied by albuminuria, anuria, and haemorrhages in the kidney substance.

Action of organic compounds of antimony. Chopra (1927) showed that the action of the organic compounds of antimony, such as urea-stibamine, is in the main the same as that of the antimonyl tartrates. Intravenous injections of most of these compounds produce a fall of blood pressure which is often more marked than in the case of tartrates. The heart becomes slow and irregular, but it gradually recovers and the blood pressure comes to its normal level. All these compounds have a depressant action on the heart, and relax the ventricles in the same way as cinchona alkaloids. There is a marked rise of pulmonary pressure. It is worthy of note that the arsenical compounds such as salvarsan also cause a marked rise of pulmonary pressure, and this is of interest in connection with 'nitritoid crisis.' Acute toxic symptoms resembling 'nitritoid crisis' are rare with the tartrates, but they are not uncommon when organic compounds are administered. It is quite likely that these symptoms are due to changes occurring in the pulmonary circulation. After an intravenous injection of organic antimony compounds, the respiration stops momentarily and then restarts, being somewhat depressed at first but regaining its normal amplitude.

On the spleen and the liver the effect of these compounds is noteworthy. In experimental animals there is a well-marked increase in the volume of the spleen accompanied by increase of rhythmic movements; the same is the case with the liver though the effect is not so apparent. The effects produced are more marked in case of the organic compounds than with the antimonyl tartrates. After injections of antimony compounds in human subjects, the patients often complain of a feeling of pain and a sensation of distention in the splenic region, and there may also be uneasiness in the hepatic region. These can be accounted for by the increase in the volume and rhythmic movements of these organs. It is possible that this increase has something to do with the therapeutic effects produced by these compounds. The spleen and the liver act as reservoirs of parasites and the influx of blood charged with antimony into these organs may contribute towards the destruction or expulsion of the parasites from these hiding places. It has been found that soon after injections of an antimony compound, Leishman-donovan bodies make their appearance in the peripheral blood where they were previously absent, showing that the action is of a provocative nature.

Antimony has a stimulating effect on the adrenals. It has been shown by Chopra and his collaborators (1928) that the residual epinephrine contents of the supra-renal glands of rabbits, who have had a course of antimony compounds, is higher than those of normal animals.

Tolerance. Continued administration of antimony to mammals does not produce tolerance as is the case with arsenic compounds.

This is due to the fact that the excretion of antimony is not diminished but on the contrary is increased. Rowntree and Abel (1917) have shown that *T. brucei* does not become 'antimony fast.' Kolmer (1926) succeeded in rendering *T. equiperdum* appreciably more resistant to antimony. Tolerance to arsenic does not confer tolerance to antimony. Some of the infusoria become resistant to the action of antimony.

Toxicity. The maximum tolerated dose of tartar emetic for rats, rabbits and guinea-pigs by slow intravenous injection of a 1.0 per cent. solution is about 0.015 gm. per kilo. body weight. For a man of 70 kilos. (145 lbs.) it corresponds to 1.05 gm.; the dose usually given to human beings at one time, i.e., 5 to 10 c.cm. of a 1.0 per cent. solution (0.5 to 0.1 gm.) is therefore well within the range of safety; such a dose would be 10 to 20 times smaller than the maximum tolerated dose and it may be safely repeated. Cases of poisoning are due to increased susceptibility of individuals and deaths have occurred from 2 grain doses given intravenously. It is, therefore, advisable to start with such small doses as 1 to 2 c.cm. of a 1.0 per cent. tartrate solution, and corresponding doses of other compounds. Repeated doses in animals produce changes in the kidneys and in the liver similar to those produced by the arsenical compounds. Epithelial degeneration has been observed, sometimes going on to fatty degeneration. Jaundice has not infrequently been noticed in kala-azar patients after a course of injections with antimony compounds and sometimes ascites has followed. The lungs may show hyperæmia and œdema. Brahmachari (1922) found marked pathological changes in guinea-pigs after toxic doses of antimonyl tartrates, consisting chiefly of hæmorrhages in the substance of the internal organs and destruction of the parenchyma of the lungs, kidneys, liver, pituitary and suprarenal glands. Similar changes are produced by the new pentavalent aromatic organic compounds.

Poisoning in man. The symptoms of acute poisoning resemble those of arsenic; these generally begin with nausea, vomiting and pain in the stomach, which is not relieved by vomiting. Emesis is violent and continuous, the ordinary contents of the stomach are first evacuated, then slimy mucous fluid which later may contain blood. In some cases no gastric symptoms are observed, but these are very rare. Vomiting is accompanied by profuse diarrhœa, followed by great muscular weakness and collapse. Prostration is intense and the patient repeatedly faints. The pulse and the respiration become slow and irregular, the skin is cold and covered with perspiration; cyanosis of the face and extremities is generally marked, and the temperature is subnormal. The patient falls into a comatose condition which deepens until after a few weak convulsive movements death ensues. The minimum fatal dose of tartar emetic in man by the mouth is difficult to estimate as the greater part of the poison is generally

removed by vomiting. Recovery has been observed after large doses, while in other cases 2 grains have proved fatal.

Chronic poisoning is very rare and difficult to diagnose. It has been observed in type-setters and is usually mistaken for plumbism. The pentasulphide is used in the manufacture of rubber, and antimony salts are also used in glazing cheap granite ware, and in this way may contaminate food stored in them. Since antimony compounds have come into vogue in the treatment of tropical diseases, symptoms of chronic poisoning are sometimes seen. These symptoms are loss of appetite, depression, headache, giddiness, anaemia, confusion, drowsiness and dimness of vision. The patient complains of a feeling of suffocation or a feeling of spasm of the glottis, discomfort or pain in the region of the stomach, general weakness and exhaustion. Profuse diarrhoea may ensue and ulceration of the small intestines round the solitary follicles and Peyer's patches has been found. The blood pressure is low and the blood shows leucopenia and eosinophilia. There may be rapid loss of flesh, dysuria, albuminuria, transient jaundice and paraplegia; pustular eruptions and sometimes collapse after extreme dyspnoea have been observed from prolonged internal use of tartar emetic.

CHAPTER XI

THERAPEUTICS OF ANTIMONY COMPOUNDS

The revival of the use of antimony is a triumph of rational therapeutics, for it was through reasoning from its chemical affinities that Cushney was led to try the remedy in protozoal diseases. Its expectorant action is taken advantage of in acute bronchitis, in which the secretion of bronchial mucus is insufficient, but it is of less value when the secretion is abundant. Its use as a diaphoretic and in respiratory diseases has now been entirely given up. Tartar emetic has been recommended in tuberculosis; keratitis has been treated with injection of tartrates; injections of the tartrates have also been given in cerebro-spinal fever. Antimony compounds have been advised instead of arsenic in the treatment of certain skin diseases. Tartar emetic ointment has been tried locally but it is very irritant and its continued use has led to diffuse subcutaneous abscesses and necrosis. This is due to the fact that the tartrates are split up by the acid secretions, forming more irritant compounds. In leprosy injections of the tartrates are said to produce beneficial effects.

Kala-azar or Visceral Leishmaniasis

Before the introduction of intravenous injections of antimony compounds the disease ran a course unaffected by treatment. Many remedies including large doses of quinine, vaccines, etc., were tried but proved useless. Whatever cures were produced were of a spontaneous nature and these have been estimated as high as 25 per cent. A concurrent attack of pneumonia or cancrum oris sometimes produces a cure. Injections of drugs, which produce leucocytosis, *e.g.*, turpentine, occasionally gave good results.

The treatment of kala-azar is now carried out with two classes of antimony preparations.

Trivalent compounds. Patrick Manson originally suggested the use of antimony salts in kala-azar but Vianna (1913)

was the first to try intravenous injections of tartar emetic, and successfully treated American forms of cutaneous and mucocutaneous leishmaniasis. Di Cristina and Caronia (1915) used this salt and successfully treated visceral forms of leishmaniasis in children, prevalent on the shores of the Mediterranean, by intravenous injections of tartar emetic. In the same year Rogers and Muir took up the treatment of Indian kala-azar with this drug and confirmed the above results. Rogers at first used a 1 per cent. solution, but later he found that a 2 per cent. solution was quite safe and more convenient. Solutions as strong as 5 per cent. can be given intravenously but they are apt to produce cough and retching, and it is not therefore advisable to use solutions stronger than 2 per cent. The solutions may be made in distilled water with or without the addition of 0.85 per cent. of sodium chloride. It is important to use freshly prepared solutions, as moulds are apt to grow and produce toxins. Solutions can however be kept for weeks if 0.25 per cent. of carbolic acid is added at the time of preparation.

Injections were given every second or third day into the veins of the arm or into the jugular vein (in children), the doses being gradually increased from 2 to 5 c.cm. of a 2 per cent. solution, keeping a watch whether nausea and gastric symptoms develop. Later, Knowles (1920) treated many cases in Assam, checking his results by spleen puncture and culture of the material for the presence of *L. donovani*. The effects were marvellous and after a few injections the fever subsided. In some cases rigors followed larger doses, but ceased after a time and the temperature remained at a low level or was normal; the weight of the patient steadily increased and the spleen diminished in size. On puncture of the spleen the number of parasites was found to be reduced; the blood showed a marked increase in leucocytes. The antimonyl tartrates are dangerous if given in doses larger than the patient can bear; the dose should be increased very gradually. Napier recommended for an average adult a primary dose of 2 c.cm. of a 2 per cent. solution (0.04 gm. of the salt), increased on each occasion by 1 c.cm., up to a maximum of 5 c.cm. (0.1 gm.); subsequently 5 c.cm. are given on each

occasion. For debilitated patients the initial dose should be 0.5 c.cm. increased by 0.5 c.cm. up to the maximum of 5 c.cm. For a child of 3 years it is advisable to begin with 0.5 c.cm. making 2 c.cm. the maximum single dose. For children of 12 the maximum is 3.5 c.cm., the doses for intermediate ages being in proportion. The dose calculated according to pounds of body weight is proportionately larger in children than in adults. The injections are given on alternate days throughout the course; they should be given at least twice a week. A routine course of 30 injections is given and a spleen or liver puncture is then done and 2 or 3 N.N.N. tubes inoculated. If no flagellates develop, and the patient's general condition and blood counts are satisfactory, he is considered cured; otherwise a further course of 10 to 15 injections is given and the puncture repeated. As a general rule it may be stated that a maximum dose of 60 grains (4 gm.) per 100 lbs. of body weight is necessary to produce a cure. This maximum course can be modified according to the general improvement in the condition of the patient, the chief factors to be taken into consideration are fever, the size of the liver and the spleen, and the blood picture. If the body weight has increased, the spleen is reduced to the level of the costal arch or at least by 4 inches, the white cell count is above 6,000 and the temperature is normal by the seventh injection, the full course of 4 gm. may be modified to 30 injections (2.88 gm.). If the temperature falls to normal by the tenth injection, 35 injections should be given; and if between the tenth and sixteenth injection, 40 injections are necessary. If this procedure is followed the cure rate is about 80 per cent.

Tolerance is quickly established, and then much larger doses can be given with corresponding beneficial therapeutic effects. In increasing the dosage, the development of tolerance should be judged from the amount of fever, cough and nausea produced. These should not be allowed to be more than slight; in fact, it may be laid down that nausea is an indication for not increasing the dose. The other important considerations are the state of the pulse, lungs and bowels and in serious cases of disease where emaciation is

marked these should be very carefully examined. Heart failure is the most serious of all the symptoms and cardiac stimulants should be freely used if necessary. Intramuscular injections of 0.5 c.cm. to 1 c.cm. of adrenalin are useful in counteracting the vasodilator effect and fall in blood pressure. If hæmorrhagic lesions occur give calcium lactate, 10 grains three times a day or 5 to 10 c.cm. of a 10 per cent. solution of calcium chloride intravenously. If œdema of the feet becomes evident the doses should be regulated with utmost caution. The treatment is continued till the temperature becomes normal. The fever does not as a rule subside before ten injections have been given. In a few cases the temperature may fall after 3 or 4 injections ; in others it may keep above normal till 40 injections have been given. A few cases show a slight rise of temperature after each injection. Among kala-azar patients the complications usually met with are diarrhoea, low blood pressure, bronchopneumonia and sloughing of the connective tissue in the form of cancrum oris. Antimony salts if used injudiciously, accentuate all these conditions, and therefore, great caution is necessary in their administration in such cases. It is of the utmost importance that when treatment is once started it should not be interrupted. Slight diarrhoea, œdema of the feet, bleeding from the gums, traces of albumin in the urine are not contraindications to treatment, in fact, they demand it. In some cases fever and rigors occur after the first injection. This is believed to be due to the destruction of parasites by the compound, as such reactions do not occur in patients who are not suffering from kala-azar, and they become less and less marked as the patients improve.

For the next five years after the introduction of antimonyl tartrates little further progress was made in the treatment of the disease in India. Sodium salts were substituted for the potassium salts and a number of purified brands of the antimonyl tartrates suitable for intravenous injection were put on the market. The greater solubility of sodium antimony tartrate makes it possible to prepare a scale form of the salt. As the purity of the salt is essential for the preparation of the scale form, it gives the practitioner greater security. With scale

preparations the severe reactions met with in the early days of treatment were minimised. A larger number of other antimony tartrates were prepared but they proved to be no more efficacious than the antimony tartrates of sodium and potassium.

Pentavalent or organic aromatic compounds. In the meantime the firm of von Heyden in Germany introduced the first pentavalent aromatic compound of antimony, sodium para-acetyl-amino-phenyl stibiate or 'stibacetin'; this was tried in the treatment of kala-azar, with promising results. Brahmachari (1922) followed up this work under the auspices of the Indian Research Fund Association and prepared a number of pentavalent compounds including urea-stibamine, which later proved to be therapeutically very effective. The introduction of these pentavalent compounds of antimony was an important advance in the treatment of kala-azar and marked the second phase in the treatment of leishmaniasis with antimonials. The advantages claimed for the pentavalent aromatic compounds according to Napier (1927) are:—

(1) These compounds are much less toxic, and can therefore be administered in larger doses. The minimum lethal dose is 15—25 mgm. per kilo. in mice in the case of the trivalent compounds, whereas it is 200 to 500 mgm. in the case of the pentavalent compounds.

(2) The total amount of antimony which is necessary to effect a cure can be administered in a much smaller number of doses. About ten doses of the pentavalent compounds against thirty doses of sodium antimony tartrate can be looked upon as the average number necessary for an ordinary case. This reduction in the number of injections means a reduction in the time the patient is under treatment from two months to about three weeks, which in its turn means that a greater percentage of the dispensary class of patients will complete a full course of treatment.

(3) Resistant cases which respond slowly when treated with the tartrates, improve rapidly with larger doses of antimony in the form of the less toxic pentavalent compounds.

(4) Certain disagreeable symptoms, such as coughing and severe joint pains, which are frequently associated with the tartrate treatment, do not occur when the pentavalent compounds are used. In a number of cases these symptoms are so severe that they necessitate the reduction of the dosage to such an extent as to prolong the course of treatment almost indefinitely and reduce considerably the chances of an eventual cure.

(5) The death rate amongst kala-azar patients under treatment has been very markedly reduced since the introduction of the pentavalent compounds. One of the most frequent causes of death during the course of treatment, namely, pneumonia, has been almost entirely eliminated.

Napier (1924) reported a death rate of 14.4 per cent. in a series of 139 cases treated with sodium and potassium antimony tartrate. The same author (1926) found the death rate to be 4.2 per cent. in a series of 167 treated in the Carmichael Hospital for Tropical Diseases, with six different pentavalent compounds.

The disadvantages of pentavalent compounds are comparatively few. The post-treatment jaundice is a little more frequently encountered, but it is not so serious as is the case with organic arsenicals. Anaphylactoid symptoms may suddenly appear towards the end of the course of injections but these are of a mild type. There is only one thing which stands in favour of the antimony tartrates and that is the high cost of the pentavalent compounds. Taking 3 gm. as the total dose necessary to effect a cure, the cost of curing a patient will be a few annas with tartrates against 6—8 rupees in case of the pentavalent compounds. This statement was made in 1927; the present price of the pentavalent compounds is much lower.

Dosage of pentavalent compounds. The initial dose suggested by the makers in the case of urea-stibamine (or stiburea), and amino-stiburea is 0.05 gm., increased by 0.05 gm. at each injection up to 0.2 gm. Napier prefers to start with 0.1 gm. for the first dose, 0.2 for the second and 0.25 for the subsequent injections. With stibosan and neostibosan

an initial dose of 0.2 gm. and subsequent doses of 0.3 gm. can be given. Children should be given smaller doses but they tolerate proportionately larger doses than adults. Infants of 18 months to 3 years of age will tolerate 0.1 gm., children of 6 years 0.15 gm. and children of ten years or over 0.2 gm. In Napier's series, with a total of 2.7 gm. of urea-stibamine and aminostiburea, the relapse rate was very low; with von Heyden 693 and 693B, a total of 3.35 gm. in 10 injections and 2.3 gm. in 8 daily injections gave good results.

Most of the compounds are supplied in sealed ampoules containing the dose required. The top of the ampoule is broken off and the contents are poured into a sterile test tube containing 3 c.cm. of sterile distilled water; not less than 3 c.cm. should be used for 0.2 gm. of the drug. This is sucked up in a sterilised syringe, and injected in the usual way. If ampoules are not available the drug is weighed on a clean piece of paper. The solutions should be prepared at the time of the injection whenever possible, but they can be kept for a few hours.

Urea-stibamine and homologues. There are several brands of this product on the market in India besides urea-stibamine (Brahmachari), 'stiburea', 'urea-stibol', 'stiburamin', have more or less the same composition and action. Brahmachari calls it ammonium carbamino-stibanilate or urea-p-tibanilate, but it has been shown by the author and his co-workers (1928) that it is not a compound but a loose combination of urea with para-amino-phenyl-stibinic acid. It was found that urea can be completely separated from the compound by repeated washing with alcohol. Besides the variation in the composition of different specimens on the market, even those prepared by the same firm vary enormously. The antimony content shows a variation from 20 to 43 per cent. Urea-stibamine is a brown amorphous powder soluble in water forming a clear yellow solution. Its toxicity is very low. The initial dose is 0.1 gm. increased by 0.05 gm. up to a maximum of 0.25 gm. given twice weekly. The patients quickly develop tolerance to the drug and its action in restoring the normal leucocyte count is rapid and most beneficial. Brahmachari found that blood became negative on culture 34 hours after a single injection in a number of cases and in 73 per cent. the blood became negative in 10 days. The average amount of the drug necessary for the cure of a case is 2.6 gm., the average number of injections is 10 to 12, and days of treatment 32 as compared with 30 to 90 injections and a total period of nearly three months in the case of antimony tartrates. The author has successfully treated patients

suffering from kala-azar with daily injections of urea-stibamine for 6 to 8 days, the first dose being 0.25 gm., second 0.3, third and subsequent doses 0.55, a total of 2.5 to 3.0 gm. being given according to the weight of the individual. The duration of treatment has thus been reduced to less than ten days. The earlier a case is treated the more effective the treatment. It is especially useful in those cases resistant to tartrates.

The solution of the drug should not be boiled and the solid drug should not be kept exposed to air.

Stibosan or von Heyden 471. This compound is chemically meta-chlor-para-acetylaminophenylstibiate of sodium. It is a light brown powder, non-hygroscopic and does not decompose in an ordinary corked bottle at room temperature. It is readily soluble in distilled water and forms a sterile solution which does not decompose readily. It was first used by Napier (1923) who gave it intravenously in 1 to 5 per cent. solution; the largest dose given intravenously was 0.5 gm., but this produced nausea and vomiting. The smallest dose which caused any symptoms was 0.2 gm. The solution should be freshly prepared and should not be heated. Generally 10 injections suffice to bring about a cure, beginning with 0.2 gm. for the first dose and 0.3 gm. for subsequent doses given on alternate days. An exceptionally weak individual should be given a starting dose of not more than 0.05 gm.; children tolerate large doses and for a child of nine years 0.2 gm. can be prescribed. The routine course is 11 to 15 injections given 2 to 3 times a week over a period of 3 to 4 weeks; 3 to 4 gm. are sufficient to effect a cure. In every case improvement is uniform and rapid and most of the unpleasant symptoms associated with injections of tartrates are absent. Stibosan is a definite compound and therefore it does not vary in composition. It does not decompose in the presence of air and it is not necessary to open a capsule every time the drug has to be given. It is contra-indicated in cases complicated with ascites but it can be given even if there is albumen in the urine, diarrhoea and chest complications. Jaundice is a contra-indication to its use.

Stibamine glucoside or Neostam. It was prepared by Henry of the Wellcome Research Laboratory. Napier (1925) treated 10 cases with this drug with good results. The compound is easily soluble in distilled water making a 4 per cent. solution and is injected intravenously in doses of 0.05 to 0.3 gm. An initial dose of 0.1 gm. and a maximum dose of 0.2 gm. are satisfactory dosage for patients of average weight. The injections are given on alternate days. The total curative dose is 2 to 3 gm.

Von Heyden 693 is diethylamine para-aminophenylstibinate. Napier tried neo-stibosan in a series of 61 cases without any deaths; fifty were cured, 2 failed to respond to treatment; the mean dose was 3.35 gm. per 100 lbs. body weight. It gave the lowest death rate and proved to

be superior to most of the pentavalent compounds now used. Ten injections produce a complete cure, the total quantity required being 3 to 4 gm. This is a stable compound and has good keeping properties. The anaphylactoid symptoms as well as jaundice are less common with this drug. There were no disagreeable symptoms, with the exception of vomiting.

Neostibosan or Bayer 693B is of the same composition as above but prepared differently; it was introduced to avoid vomiting. This compound forms an isotonic solution in 25 per cent. concentration and can be given effectively by the intramuscular route; 0.3 gm. can be given by daily injection and 8 injections, *i.e.*, a total of 2.4 gm. suffice to cure the disease. There is entire absence of nausea and vomiting and the patients tolerate the maximum dose from the very first injection.

Amino-stiburea. Chemically it is p-aminophenylstibinic acid combined with urea and glucose. The addition of glucose is said to add to the stability and to the diffusibility of the drug. This compound is quite effective against leishmaniasis. The total quantity required to produce a cure was 3.35 gm. per 100 lbs., that is, about the same as other pentavalent aromatic compounds.

Relative value of pentavalent compounds in the treatment of kala-azar. The sterilising dose per kilo. body weight of patients according to Greig and Kundu (1925) works out to be 0.054 and 0.06 gm. for urea-stibamine and stibosan respectively; the curative value is about the same. The number of injections in the case of all pentavalent compounds was nearly equal but was lowest with neostibosan. The average number of injections before the fever subsided was as follows:—Stibosan (No. 471) 5.6, satibamin glucoside 5.4; urea-stibamine 5.1; neo-stibosan (No. 693) 4.57; aminostiburea 4.48. Stibosan and neostibosan are the most stable compounds. Neostibosan is the most innocuous and produces a cure in the shortest period; it gives the lowest death rate during treatment. Patients can now be cured with a routine treatment of eight daily injections of 0.3 gm. of neostibosan.

The course of the disease under treatment. The fever usually subsides after the fifth injection, or even earlier but it may persist for a fortnight or more. In most cases the downward tendency of the temperature is immediately apparent, in some cases the temperature remains at about 100°F throughout the course of injections, only coming to normal when the course is discontinued. In some patients a reactionary rise

after each injection is observed. A sudden sharp reaction means that the dose has been too big.

The general condition of the patient begins to improve soon after the injections are started; the weight may decrease slightly at first but then rapidly increases during the course. The hair ceases to fall out and regains its normal lustre; the appetite improves and there is a sense of well-being. In women menstruation usually begins when the course of treatment is ended. The spleen diminishes rapidly in size and in most cases disappears below the costal margin at the conclusion of the treatment. In some patients the effect on the spleen is slower and in others it is only appreciable when the course of injections is nearing completion. The behaviour of the spleen is dependent on its consistency; when it is fibrous and hard, diminution beyond a certain limit is not possible. The liver seldom shows any tendency to decrease until after the injections have been completed.

The blood picture improves rapidly and by the time the course is completed the leucocyte count is normal or may even indicate leucocytosis; there is a noticeable increase in the eosinophiles; the erythrocyte count also shows an increase.

No dose, however large, can be guaranteed to produce a 100 per cent. cure rate. A spleen or liver puncture gives the best indication of cure but it should be remembered that the effect of antimony continues for some time after the last injection. This is shown by the fact that patients who show Leishman-donovan bodies on spleen or liver puncture become entirely negative some weeks later. The best plan is to give a full course of injections and if there is a relapse a more intensive second course should be started.

Relapses. If the full amount of the drug has been given relapses are not very common; they are only frequent after insufficient treatment. There is no evidence to show that patients who have had previous injections of antimony require much bigger doses to eradicate the disease in the event of a relapse, but the disease in some cases is much more resistant and these require larger doses. When a relapse occurs the patient should be given a much more thorough course of treatment. A

definite enlargement of the spleen usually accompanies a real relapse as distinguished from other forms of fever. In relapses after antimonyl tartrates one of the pentavalent compounds should be tried.

Antimony fastness of leishmania. It has already been stated that trypanosomes may be rendered resistant to antimony though not to the same extent as to arsenic. The same possibility exists in relation to the treatment of kala-azar. It is recommended that the doses of the antimony compounds should be increased and intervals between injections made longer when this condition is developed.

Antimony in pregnancy. Antimony compounds in therapeutic doses have no marked effects on the gravid uterus. Treatment therefore should not be withheld in any stage of pregnancy. Many pregnant women treated with antimony go on to full term and give birth to healthy children.

The evidence of cure. The best evidence of cure is the absence of all symptoms of the disease during at least six months following the course of treatment. It has been shown that even though cultures from the spleen and liver puncture are positive weeks or months after the completion of treatment the patient may still attain a cure.

A number of tests introduced recently for the diagnosis of kala-azar may be employed as evidence that cure has been effected.

1. **Napier's aldehyde reaction.** This test consists of adding one drop of 40 per cent. formaldehyde to 1.0 c.cm. of serum in a test tube. The mixture is then shaken and allowed to stand at room temperature. Within 3 to 20 minutes the serum becomes absolutely solid and opaque. This test is positive in 83.5 per cent. of cases. When the patient is cured this test becomes negative.

2. **Chopra's antimony test (Serum test).** Whole serum and serum diluted 1 in 10 with distilled water are put in miniature test tubes ($2\frac{1}{2}$ to 3 inches long made by sealing one end of a piece of glass tubing 4 to 5 mm. in diameter) with a capillary pipette. A 4 per cent. solution of urea-stibamine

made with distilled water is then slowly run along the side of the tubes. A heavy coarsely-flocculent precipitate forms when the antimony solution comes in contact with the serum. Tartar emetic does not give this reaction but stibosan does. During treatment with pentavalent antimony compounds the test becomes uncertain at first and then, after the full course of treatment, it is negative. In very early cases 1 in 10 dilution of the serum may give negative results and whole serum should be employed. A correct diagnosis can be made by this test in 88.2 per cent. of cases as compared with 83.5 per cent. of the aldehyde test.

Finger prick blood test. A drop of blood from the cleaned finger is received into a small test tube ($\frac{3}{8}$ inch internal diameter and 2 inches long) containing 0.25 c.cm. of a 2 per cent. solution of potassium oxalate. The corpuscles are allowed to settle down and the test is performed with the supernatant fluid. A 4 per cent. solution of urca-stibamine is added in exactly the same way as in the serum test. A flocculent precipitate means a positive test. The reading should be taken from 5 to 10 minutes after mixing the solution. A positive test is obtained in 86.4 per cent. of cases. Both these tests become negative when the patient is cured.

(3) **Lloyd and Paul's test.** In normal serum there is on the average 0.16 gm. of euglobulin per 100 c.cm. of serum or approximately 5 per cent. of total globulin; in well-established cases of kala-azar it is 1.5 to 2.5 gm. per 100 c.cm., i.e., 40 to 50 per cent. of the total globulin. Lloyd, Napier and Paul applied the method of protein graphs to estimate the cure of kala-azar after treatment with antimony compounds. The protein fraction estimations are made by the refractometric method described by Robertson (1924). There is a steady ascent of the pseudo-globulin and a steady descent of euglobulin, and finally euglobulin attains the normal figure of approximately 0.16 gm. per 100 c.cm. of serum when there is complete cure. The graphs give an index of the condition of the disease. It is suggested that high globulin content of serum in kala-azar is an immunity response and such cases react to treatment

rapidly, while the low protein type of case with a weak aldehyde test represents the opposite condition.

(4) **Chopra and Choudhury's test.** By noting the time of gelation with formalin of the sera from the blood of kala-azar patients, it is possible to indicate in a general way, the progress towards cure. Information regarding progress towards cure may be said to be satisfactory, if the time of gelation is more than half an hour. If however the time of gelation before treatment is known, and this can be easily determined from an aldehyde test, the corresponding increase of the time of gel formation also gives useful information.

Antimony in Other Affections

Syphilis. Niesser was the first to suggest the employment of antimony compounds in the treatment of syphilis. Monkeys can be rendered immune by injecting organic compounds of antimony but metallic antimony and antimonyl tartrates of sodium and potassium are less effective. The curative effects of antimony preparations in syphilis in rabbits has been studied. After tartar emetic in doses of 0.01 gm. per kilo. intravenously, the lesions showed only non-motile spirochaetes the following day, but active organisms were again found on the third day. On the whole, it appears that antimony possesses but a feeble toxic action against the spirochaetes. Syphilis in man has been treated with injections of tartar emetic (1 in 1,000) and although it improves certain manifestations, it does not appear to have any marked effect on the progress of the disease.

Framboesia. Injections of antimonyl tartrates have been tried in jaws, but there was no marked effect even after 8 to 10 injections.

Malaria. Rogers originally suggested the use of antimonyl tartrates in the treatment of malaria. It was at first thought that injections of these compounds destroyed the asexual parasites as well as the sexual forms which were unaffected by quinine. Further work showed that the tartrates or the organic compounds have little or no action on the malarial parasites.

Granuloma inguinale is a disease endemic in many tropical countries. It was thought to be produced by an organism which was first described by Donovan, and believed by some to be a protozoon and which recent work has demonstrated to be a non-motile capsulated bacterium of the rhinoscleroma group called *Calymmatobacterium granulomatis*. This organism however has not been definitely proved to be the cause of the disease. Injections of antimonyl tartrates as well as thio-glycollate of antimony have given good results in this condition.

Antimony in helminthic infections (see Helminthic Diseases).

Rat-bite fever. Injections of stibosan have been tried in this condition with beneficial effect. Neither tartar emetic nor stibenyl produces any effect.

Trypanosomiasis. Antimonyl tartrates have a remarkable effect in diseases produced by trypanosomes in animals. It was found that 1 mgm. of antimony caused immediate disappearance of the parasites in rats weighing 200 gm. Plimmer and Thomson (1908) noticed the sterilising effects of potassium and sodium antimonyl tartrates in laboratory animals infected with *T. brucei*, and *T. evansi*. Rats inoculated with nagana died in an average time of 5 to 6 days; if on the fourth day, when the blood was full of parasites, 5 mgm. of tartar emetic were injected subcutaneously the parasites were killed, the rats usually survived and some recovered completely; relapses, however, not infrequently occurred. Arsenic and some aniline dyes produce the same type of effect but are inferior to antimony compounds in this respect. Triamide of antimony thioglycollic acid was found to be quite effective against *T. brucei*, *T. evansi*, and *T. equiperdum* in rats, dogs and rabbits. Antimony triamide in 30 per cent. suspension in oil was tried intramuscularly with success in trypanosome infections, including *T. gambiensi*; a large number of other antimony compounds were also tried in the treatment of this infection in animals and rapid disappearance of the parasites after intravenous injections, was observed. The effects were so rapid that there appears to be little doubt that the trypanocidal action is due to antimony and not to the formation of antibodies. No evidence of agglutination or phagocytosis has been found; the parasites are first rendered incapable of multiplication and then rapidly die. The trivalent compounds are much more effective in this respect than pentavalent compounds. Nothing is known regarding the immunological factors in relation to the trypanocidal activity of the antimonyl compounds, but Kolmer is of opinion that in animals successfully treated, a period of immunity follows.

Antimony compounds were first tried in the treatment of human trypanosomiasis many years ago. Borden (1910) successfully treated sleeping sickness in the Congo with injections of tartar emetic. Kerandel successfully treated himself with injections of tartar emetic after failing with atoxyl. Owing to the chronicity of the disease, and the great tendency to relapse after long intervals of absence of the parasites from the peripheral circulation, it is very difficult to draw any conclusion regarding the curative effects of the drug. The successful treatment of trypanosomiasis entails strict control over the patient, possibly for two years. Moreover, the stage

at which the treatment is adopted is an important factor to be taken into consideration. If the cerebrospinal system is affected no form of treatment will check the almost inevitable steady progress towards a fatal termination. Another difficulty is that the treatment has to be protracted because as much as 500 grains of tartar emetic are required to destroy the trypanosomes. The administration of such large quantities may take a year or more, and this affords the parasite the opportunity of permanently damaging the nervous tissues. Intravenous injections of antimonyl tartrates of potassium and sodium are undoubtedly worthy of trial in this disease; the pentavalent aromatic compounds of antimony have not proved effective in this condition. Preparations containing azo-dyes and antimony have been tested on laboratory animals but results are not encouraging.

Dermal and muco-cutaneous leishmaniasis. Under this heading are included oriental sore and generalised dermal leishmaniasis, both of which occur in India, and the muco-cutaneous form or *espundia* which occurs in South America. The parasites responsible for these conditions are culturally and morphologically indistinguishable from those of kala-azar. Oriental sore is produced by *L. tropica*, the organism occurring in the thickened edges of the sore. The distribution of oriental sore is in marked contrast to that of kala-azar, as the former occurs only in north-western parts of India, Mesopotamia, and Asia-minor where kala-azar is not met with. Ulcerative conditions commonly occur in dogs in the endemic areas of oriental sore, in Tehran, Algiers, Aleppo, etc. Chronic cutaneous leishmaniasis can be produced by inoculating mice on their tails with a few drops of *L. tropica* cultures. *P. papatasi* is probably the carrier and those flies fed on sores become infected. Direct inoculation at the time of biting rather than the contaminative method through parasites in the flies' excreta, produces infection. *Espundia* has a wide distribution in the tropical portions of South America. The transmission has not been worked out but *P. lutzi* is suspected. The ulceration occurs in oro-pharyngeal mucosa with extensive involvement of the nose and throat; many cases resemble oriental sore. For the dermal infection, which is a sequel of

kala-azar, intravenous injection of antimony compounds is considered by Napier (1927) to be the only treatment and cases in which there was no previous history of kala-azar cleared up rapidly, usually about ten injections being necessary. The cases which have been previously treated for kala-azar are much more resistant and even 5 gm. of stibosan may have no effect.

Oriental sore may heal in 6 to 18 months without treatment and intravenous injections of tartar emetic are regarded as a drastic procedure. If antimony is used the line of treatment is the same as in kala-azar, 10 to 20 injections making a total of 2 to 3 gm. of tartar emetic suffice in most cases. Pentavalent compounds of antimony have also been used with good results. X-rays and antimosan have been considered by some to be very effective. A 2 per cent. ointment of tartar emetic in paraffin and ionization with such ions as zinc, iodine, etc., carbon dioxide snow, methylene-blue ointment, strong solutions of zinc sulphate, powdered potassium permanganate have been administered and are sometimes successful.

Besides antimony other drugs have also been tried in *L. tropica* infection. It has been shown that berberine sulphate in dilutions of 1 in 80,000 inhibits the growths of *L. tropica* and *L. donovani*, while quinine and emetine in 1 in 1,000 dilution have little or no action. One-third of a grain (0.02 gm.) dissolved in 1.5 c.cm. of distilled water is injected round the base of the sore. Injections are given at weekly intervals and solutions must be freshly prepared; after injection a dressing of hypertonic salt solution is applied. Healing takes place in 5 to 14 days as compared with 18 days of tartar emetic treatment. Not more than one or two sores should be treated at one time. Emetine hydrochloride injected locally around the edge of the sore produces healing. Doses of 0.15 grains (0.01 gm.) are given to start with, increased 5 to 10 times according to the size of the sore, and healing takes place in 15 to 30 days. Twenty minims of a 5 per cent. solution injected into the edges make the sores well defined in 3 to 4 days and healing takes place in a short time.

The muco-cutaneous form is more resistant to antimony than infections with *L. donovani*. Injections of Martindale's oxide of antimony, trioxide of antimony as a local application, ointments of stibenyl and stibosan, have all been used with good results. Fouadin intramuscularly is said to heal the lesions rapidly. For adults the doses recommended are 1.5 to 3.5 c.cm. for the first 2 injections, subsequently 5 c.cm. There is no local pain or reaction, 20 to 30 injections may have to be given. Eighty per cent. solution of lactic acid has been found by some to be superior to antimony injections. Stovarsol, Bayer 205, antimosan, iodobismuthate of quinine, amino-arseno-phenol have been tried with varying degrees of success, but no specific treatment has been discovered.

Modes of Administration

By the skin. A five to ten per cent. ointment of metallic antimony in lanoline base was recommended in the treatment of leishmaniasis, one drachm being rubbed over the abdomen every second or third day. It has no appreciable effect on the course of the disease. Oriental sores have been successfully treated with a 2 per cent. ointment of tartar emetic, the application being made at night. The irritant action of tartar emetic when applied to the skin in the form of an ointment is due to its being broken up by the acid formed by decomposition of the sweat. If sodium bicarbonate is added to the ointment the irritating effects are considerably reduced.

By mouth and per rectum. The antimony salts are not suited for administration by the mouth except in very minute quantities. Their irritant action gives rise to emesis and they are not easily absorbed from the alimentary canal. Before the discovery of the pentavalent organic compounds, intravenous injections were supplemented by oral administration of tartar emetic but it was not well borne. This route cannot be adopted when it is necessary to introduce large amounts into the body as in cases of protozoal diseases.

Rectal injections of tartar emetic, urea-stibamine, etc., have been tried; the former salt is too irritating and causes much pain and discomfort. The latter is not so irritating but

the quantity absorbed by this route is too small to produce a concentration in the blood lethal for leishmania.

Subcutaneous and intramuscular methods. Subcutaneous injections always produce cellulitis and abscess formation.

Intramuscular injections even of the double salts are very irritating, not only is severe pain produced but extensive necrosis of tissues at the site of injection occurs. Attempts have been made to discover preparations which can be given this way without harmful effects. Martindale's solution of the oxide in glycerine and water gave variable results. Colloidal sulphide of antimony in suspension, hyperacid antimonyl tartrate, urea-stibamine, and stibacetin, have been tried intramuscularly. Although they do not produce much pain, absorption of antimony is irregular and is not sufficiently large to produce a concentration in the blood, lethal to the parasites. Such compounds as antimosan, fouadin, stibosan and neostibosan administered by the intramuscular route are said to be quite effective. The advantages of this method are that, as compared with the intravenous route, little skill is required; besides, in very young children it is sometimes impossible to get at the veins embedded in the subcutaneous tissue.

Intravenous route. The intravenous method of administration is the only method by which uniform success can be claimed and most of the antimony compounds can be introduced direct into the blood stream with safety. The only objection is that it requires special technical skill, but that can be easily attained with a little practice. It has been asserted that intravenous injections are painful, and some have gone so far as to say that they are dangerous and that one is not justified in using this method, especially in mild diseases like oriental sore. Experience has, however, amply proved that the danger is slight if proper care is taken as regards technique and regulation of dosage of these compounds. The technique of intravenous injection is described in the chapter on intravenous therapy.

CHAPTER XII

COMPOUNDS OF ANTIMONY

Like many metals antimony forms two series of compounds, its valency varying from three to five.

Antimony compounds may be classified as (1) Inorganic salts. (2) Organic salts, e.g., antimonyl tartrates are trivalent compounds. (3) Organic compounds.—(a) Trivalent, these are unstable. (b) Pentavalent, these are stable and are commonly used.

Chemotherapy of antimony compounds. Uhlenhuth and his colleagues (1925) tested antimony compounds on mice infected with dourine, intraperitoneal injections of the compounds being made on the third day after infection. They tested two groups of antimony compounds, and their results, based on one injection in each case, are as follows:—

(1) The first series constitute the phenyl stibinic acid derivatives which are therapeutically active and in which antimony is united directly to carbon. Drugs belonging to this group are stibenyl and stibosan. In this series antimony is pentavalent.

(2) In the emetic series antimony is linked to oxygen and only through oxygen to the carbon. In these compounds antimony is trivalent; antimosan is a member of this group.

In the first series it is recognised that variation in the toxicity and therapeutic activity is possible by substitution of one or more of the hydrogen atoms in position 2 and 6 in the ring, by other atoms or groups such as chlorine (Cl) or amino (NH_2) or hydroxyl (OH) groups. Comparatively slight changes in the structure of these compounds produce considerable differences in their toxicity and therapeutic action. For example, substitution of a chlorine for a hydrogen atom in position 3 changes stibenyl into stibosan while by increasing the toxicity (M.L.D. 5 instead of 12 mgm.) the curative power is also increased, the dose usually being 2 mgm. in the place of 5 mgm.

The replacement of the acetyl-amino-group of stibenyl by chlorine increases, on the contrary, the toxicity and at the same time destroys its trypanocidal action. In the emetic series there are three components, the base potassium, the active element antimony and the acid radicle, tartaric acid. All these components can be and have been varied and in general it has been supposed that no matter how the base and the acid radicles are varied, the toxicity and therapeutic activity are determined solely by the amount of antimony present, though when potassium is replaced by a therapeutically active base such as quinine, there may be additional activity due to the quinine.

It is pointed out that by making the acid radicle a catechol (1-2 dihydroxy-benzene) derivative, definite variation in the action of the antimony becomes possible without further changes in the constitution of the molecule. In addition the products are stable to alkali and can be injected intramuscularly as well as intravenously. Antimosan produced in this way has an M.L.D. of 8 mgm., 1 mgm. causes the disappearance of trypanosomes from dourine-infected mice in three hours but they return in 10 to 15 days; an initial dose of 2 mgm. causes their disappearance without return. Tartar emetic was found to have an M.L.D. of 0.8 to 1.0 mgm. Trypanosomes disappear after a dose of 0.5 mgm. but return in from 13 to 20 days, and with one exception it was not found possible to ensure their complete disappearance. Antimosan has been tried clinically but is found to be less effective than stibosan in kala-azar though good results have been obtained in multiple sclerosis.

1. **The inorganic compounds.** Only a few of these are used in therapeutics. Two sulphides of antimony are well known, the black sulphide or trisulphide Sb_2S_3 and the golden sulphide Sb_2S_5 . Antimony sulphuratum is a mixture of various sulphides and oxides and is an orange-red powder; the dose is 1—2 grains. Antimony forms 3 oxides, (1) antimony trioxide Sb_2O_3 (2) Antimony tetroxide Sb_2O_4 and (3) Antimony pentoxide Sb_2O_5 . Antimony oxide Sb_2O_3 is a heavy white powder and is used in solution in glycerine. Metallic antimony in a fine state of subdivision as an impalpable powder, colloidal antimony and antimony sulphide in a colloidal state have been used by intramuscular injections in leishmaniasis and other protozoal affections, but their therapeutic action is not marked. A 5 per cent. ointment of powdered metallic antimony has been prepared and used.

2. **The organic salts or the trivalent compounds.** Of these antimonium tartaratum or 'tartar emetic', which was discovered in 1631, is well known; sodium antimony tartrate is also an old compound. The dose is $\frac{1}{2}$ to 2 grains intravenously usually in 1 or 2 per cent. solution. Hypodermically they are both very irritating. Potassium antimonyl tartrate $[\text{K}(\text{SbO})\text{C}_4\text{H}_4\text{O}_6]_2\text{H}_2\text{O}$ occurs in crystals and is soluble in 17 parts of cold water but it is almost insoluble in alcohol. It contains 36.17 per cent. of antimony as compared with 38.01 per cent. which is contained in sodium antimony tartrate and 36.51 per cent. in the ammonium antimony tartrate.

Sodium antimonyl tartrate was originally tried by Thomson, who was struck by its effect on trypanosomes. Rogers' experiments on pigeons and rabbits showed that the sodium salt is less toxic than tartar emetic and also the local irritant effects are less marked. The properties, therapeutic and other effects of this compound are the same as 'tartar emetic'. It is also known by the name of 'stibinol'.

An alkaline solution of sodium antimony tartrate known under the name of 'neostibinol', is said to be less toxic but equally efficient.

Antimony aniline tartrate occurs in white crystals and is soluble in 7 parts of water. It is claimed to have a low toxicity after hypodermic injections and is said to possess a considerable activity against trypanosomes. Sulphoform or triphenyl-antimonii-sulphide has been used in skin diseases, antimony thioglycollamide and antimony sodium thioglycollate have been prepared and have proved effective against experimental trypanosomiasis in rats, dogs and rabbits.

3. Aromatic compounds of antimony. (a) *Trivalent.* A large number of antimony analogues of the organic arsenicals have been prepared. The trivalent compounds, i.e., the analogues of salvarsan, are not only difficult to prepare, but also are less stable and not easy to purify. None of them fulfil any of the conditions necessary for an efficient trypanocide. These are: firstly, the compound must be non-irritant and capable of forming a perfect solution at the temperature of the body and at the alkalinity of the tissues; secondly, it should act as a parasiticide quickly, so that there is not sufficient time for tolerance to be developed; and thirdly, when the parasites have once been expelled from the blood there should be no recurrence in the majority of cases. None of these compounds have been found to satisfy these conditions.

(b) *Pentavalent.* The origin of the aromatic antimonials is due to the work of Michaelis and Reese whose investigations led to the preparation of triarylstibines. Later, Grignard's reaction gave rise to the preparation of triphenyl-stibamines. The present development of the organic antimony derivatives is, however, mostly due to the work done by Professor Schmidt of Chemische Fabrik von Heyden who discovered the process of introducing into the aromatic nucleus the antimonial group, through the agency of the diazo-reaction. Great impetus was thus given to the synthesis of aromatic antimonial drugs and most of the antimony analogues of the aromatic arsenical drugs such as atoxyl, salvarsan, etc., were prepared. From aniline by diazo-synthesis it was quite easy to prepare phenyl-stibinic acid and then para-amino-phenyl-stibinic acid (p-stibanilic acid), which is the antimony analogue of p-arsanilic acid. Its sodium salt, sodium para-amino-phenyl-stibinate (or sodium-stibanilate) is the antimony analogue of the arsenical compound known as 'atoxyl' or 'arsamin' (sodium p-arsanilate). This compound was later given the name of *stibamine* by Brahmachari from its analogy to the corresponding salt of arsenic which is called *arsamin*. A derivative of this, sodium acetyl-p-amino-phenyl stibinate, was called 'stibacetin' which was one of the earlier members of the aromatic series to be used in the treatment of leishmaniasis under the name of stihenyl. This compound is soluble in water, it is stable and does not irritate the tissues to the same extent as do some of the organic antimony compounds, so that it can be given intravenously as well as intramuscularly.

Unfortunately, however, it has not proved of any great therapeutic value in kala-azar in this country.

The sodium salt of p-amino-phenyl-stibinic acid, or sodium p-amino-phenyl-stibinate (stibamine of Brahmachari) is also a soluble compound which, though therapeutically active, is unfortunately not very stable. Its therapeutic application is therefore limited. Brahmachari (1925) prepared the carbamide derivative of p-amino-phenyl stibinic acid by warming p-amino-phenyl-stibinic acid suspension in water and urea until the acid is almost dissolved; this is concentrated on a water-bath and the salt is precipitated by the addition of alcohol. The resultant substance, urea stibanilate or ammonium carbamino-stibanilate, was called 'urea-stibamine.' This substance is a pentavalent compound of antimony and Brahmachari believes it to be a substituted urea and not a urea salt of stibinic acid. The constitutional formula given by Brahmachari has however been doubted and criticised. This compound has also been prepared and sold under the name of stiburea, urea-stibol, stiburamin.

The combination of urea with p-amino-phenyl-stibinic acid renders the latter compound more stable and soluble (p-amino-phenyl-stibinic acid is not soluble) and at the same time, it is more efficacious therapeutically. It is a well-known fact that when quinine is combined with urea, its solubility and diffusibility are considerably increased, and the resultant compound is able to penetrate better into the tissues; its local anæsthetic action is also much enhanced. Similarly, better penetrability of these compounds probably accounts for the superior therapeutic results obtained by them as compared with the previous compounds.

Von Heyden a few years ago, introduced a compound, metachloro-para-acetyl-amino-phenyl-stibinate of sodium (chloro-stibacetin or von Heyden 471) under the trade name of 'stibosan'. The same firm later introduced two other compounds diethylamine-para-amino-phenyl-stibinate (von Heyden 693) and neostibosan (von Heyden 693 B). Both these compounds were tried by Napier (1923 and 1927) and gave very good results in the treatment of kala-azar. They are much more efficacious than some of the earlier organic aromatic compounds of antimony such as stibenyl and are at least as effective, if not more, than urea-stibamine.

Stibamine has also been combined with glucose and a preparation 'stibamine glucoside' also known as 'neostam' is on the market. A number of other organic antimony compounds are available and some of them have been tried with success in the treatment of kala-azar. One of these compounds is p-amino-phenyl-stibinic acid combined with urea and glucose, which has been prepared by a Calcutta firm and sold under the trade name of 'amino-stiburea'. Most of the antimony compounds in use at present are not very stable in the air, even in a solid condition and in solution some of them change very rapidly.

The following table briefly gives the modes of administration and therapeutic effects of various pentavalent compounds of antimony.

Pentavalent Compounds of Antimony

Nature of compound.	Trade name.	Makers.	Remarks.
Salts of para-amino phenyl-stibinic acid. Sodium p-amino-phenyl-stibinate or sodium stibanilate.	'Stibamine'	von Heyden.	Not stable and therefore not used.
Diethylamine para-amino-phenyl-stibinate.	No 693 & 693 B. Neostibosan.	von Heyden. Bayer Meister Lucius.	Very effective in kala-azar.
Derivatives obtained by substitutions in the amino-groups of para-amino-phenylstibinic acid.	Urea-stibamine Stiburea. Urea-stibol.	Brahmachari.	An effective remedy against kala-azar.
Urea combined with p-amino-phenyl stibinic acid (ammonium para-carbamyl-amino-phenyl stibinate.)	Stiburamine.	B.C.P.W.	
Acetyl-p-amino-phenyl stibinate of sodium. Nitrogen glucoside of sodium p-amino-phenyl-stibinate. Para-amino-phenyl-stibinic acid combined with urea and glucose.	Stibenyl. Stibacetin. Stibamine glucoside. Neostam. Aminostiburea	von Heyden Burroughs Wellcome & Co. Union Drug Co., Calcutta.	Tried in kala-azar but less satisfactory.
Derivatives obtained by substitutions in the benzene nucleus of para-amino-phenylstibinic or para-acetyl amino phenylstibinic acid.			
Meta-chlor-para-acetyl-amino-phenyl stibinate	No. 471 Stibosan.	von Heyden.	Effective, but now superseded by Neostibosan.

Table of Toxicity of Antimony Compounds

Name.	Minimum lethal dose in mgm. per kilo. of mice.	Maximum tolerated dose in mgm. per kilo. of mice.	Percentage of antimony.
Potassium antimony tartrate ...	16
Sodium antimony tartrate ...	20
Stibacetin and stibenyl ...	133	...	33
Urea-stibamine, Stiburea, Ureastibol	250	175	20—43
Stibosan or von Heyden 471 ..	275	200	31
Stibamine glucoside. Neostam ...	500	300	30
Aminostiburea	250	...	24.8
Von Heyden 693 & 693 B. Neostibosan	350	250	40

The pentavalent compounds can now be therapeutically tested on the striped Chinese hamster *Cricetulus glesus* or the European hamster *Cricetulus frumentarius* both of which can be easily infected with leishmania. The chemotherapeutic index of some of the compounds is as follows:—

Antimosan 1: 5, Stibosan 1: 5 to 1: 7 and Neostibosan 1: 50

CHAPTER XIII

TOXIC EFFECTS

A. Complications due to antimonyl tartrate injections

Certain toxic symptoms follow injection of antimonyl tartrates. Of all the symptoms according to Christopherson (1921) cough, metallic taste and a feeling of tightness in the chest are most frequent. Cough, retching and colic indicate a need for caution. Jaundice and a larger amount of albumin in the urine than can be accounted for by the disease are signs of danger. So far as is known acute toxic reactions of the 'nitritoid crisis' type do not occur with antimonyl tartrates. The toxic symptoms that are produced may be grouped as follows:—

1. **Gastro-intestinal and respiratory.** Severe coughing may occur immediately after the injection and may be so severe as to end in vomiting. It is an indication that the dose has been excessive and should not be increased. After a large dose the patient may vomit 5 or 6 times. By decreasing the dose and then gradually increasing it, a certain degree of tolerance can be established. Both coughing and vomiting may be induced by giving the injection on a full stomach or by giving it rapidly. In some cases a violent fit of coughing has followed even the smallest doses and recurs with each injection. Delayed vomiting may start 4 to 5 hours after injection, acute diarrhoea may sometimes follow, a metallic taste may be noticed after injection. Codeine $\frac{1}{4}$ grain or a few minims of adrenalin given a quarter of an hour before the injection will reduce the tendency to vomiting. Pneumonia and lung complications occur frequently with antimonyl tartrates but they are extremely rare with the pentavalent compounds. If a very large dose is rapidly given the respiration may stop.

2. **Cardiac symptoms.** These consist of cyanosis, rapid and irregular pulse, a choking feeling in the chest and tachycardia. Marked slowing of the heart has occasionally

been noticed towards the end of the course. During the injection there is hardly any fall of blood pressure.

3. **Cerebral symptoms.** These are said to occur more commonly during treatment of trypanosomiasis. Loss of consciousness with incontinence of urine and fæces may sometimes ensue. Severe headache or hemicrania has been observed after 6 to 9 injections and it does not clear up till the injections are discontinued.

4. **Arthritic symptoms.** Severe joint and muscular pains frequently occur but are less common towards the end of the course. Pain in one or both shoulders, and lumbago are common complications; the wrist joint, knee joint and ankle joint may be affected and the pain may last for some time. Usually the joint pains commence 4 to 6 hours after an injection, generally after a total of about 10 grains of antimony tartrate and they last for about 12 hours. Ten grains of aspirin given half an hour before the pains are expected to begin, diminish their severity. Codeine in $\frac{1}{2}$ -to 1 grain doses counteract most of these symptoms.

5. **Other symptoms.** An irritating papular eruption of the skin may occur on any part of the body. A sharp rise of temperature with rigor is generally due to injection of faulty solution. Profuse sweating or fainting is of rare occurrence.

B. Complications after injections of pentavalent compounds.

The fit of coughing which not infrequently occurs after injection of antimonyl tartrates does not, as a rule, occur with the organic aromatic compounds. Nausea and vomiting are seen in about 10 per cent. of cases, but rarely with neostibosan (von Heyden 693 B) except when the dose is very large. If nausea and vomiting persist the dose should be reduced. The tendency to vomiting can often be overcome if the dose is increased very gradually. After injections of stibosan vomiting not infrequently occurs, and this is a serious drawback. Generally the vomiting begins within 20 minutes of the injection and it may be preceded by giddiness. If the patient remains quiet in bed vomiting may be avoided. The injections should

not be given immediately after a meal. Diarrhoea may occasionally occur towards the end of the course and may be severe. The motions are dark, watery and frequent; they contain no blood or mucus. Fatal collapse and death are on record. A severe attack of shivering lasting for 2 hours may be the only feature. Cardiac, cerebral and arthritic symptoms have not been noticed.

Symptoms of an anaphylactoid nature resembling the 'nitritoid crisis' (occurring with organic arsenicals) sometimes develop. 'This is to be expected as both these series of compounds are of semi-colloidal nature and give rise to changes in the blood; they also produce an enormous rise of pulmonary pressure. These symptoms set in suddenly after the sixth or seventh injection, when the patient has been receiving maximum doses. Within a few minutes of injection the face becomes puffy, the voice husky, there may be an urticarial rash on the body, dyspnoea and stertorous breathing. The patient has a feeling of impending death. The pulse becomes weak and imperceptible, the patient is cyanosed and coma and collapse may soon supervene. The condition though alarming, is rarely fatal and as a rule all symptoms disappear in two hours; puffiness of the face may last for 24 hours. In Napier's series, these symptoms were more frequently observed with aminostiburea and urea-stibamine and were rare with neostibosan. Injections of a few minims of adrenalin or pituitrin relieve the symptoms. If these symptoms occur it is best to abandon treatment with a particular compound, recommencing it with minute doses of some other compound.

It has already been pointed out that agglutination and hæmolysis of red blood corpuscles do not occur even with concentrated solutions of the antimony compounds. These symptoms therefore cannot be due to embolism of the capillaries of the lungs and other organs. Chopra and his associates (1927) have shown that when organic antimony compounds come in contact with the serum of kala-azar patients a thick flocculent precipitate is formed; this precipitate is not produced with non-kala-azar serum and this reaction has been used as a diagnostic test for the disease. It is possible that some of

the untoward symptoms produced may be due to this precipitation.

Rarely, acute congestion of liver or even symptoms of acute hepatitis are produced by injection of these compounds. The liver becomes enlarged, tender and painful ; the temperature rises and there may be jaundice. The symptoms disappear if the injections are stopped and are apparently due to the toxic action of the compounds on this organ. Jaundice may sometimes appear 1 to 3 months after the course. Dermatitis of an exfoliative nature has not been noticed.

Choice of a compound. The chief factors to be taken into account in the selection of a compound are the toxic effects produced, the time necessary to produce a cure, the ease of administration and the relapse rate after treatment. Anaphylactic symptoms are common with urea-stibamine and amino-stiburea, but are rare with stibosan and neostibosan. The relapse rate is also lower with the latter compounds and they are more stable. Neostibosan is the easiest to administer as it can be given intramuscularly in doses of 0.1 gm. to 0.3 gm. without causing pain and it is effective. Both these compounds are, however, expensive. Urea-stibamine and allied compounds are nearly as effective and are slightly cheaper.

Cumulative action. Cautions and contra-indications. The human body can stand large doses of antimony especially when it is given intravenously. The reason for this is that when administered by this route large quantities are eliminated from the system by the kidneys.

Antimony salts should be employed with great caution in weak, anæmic and emaciated subjects. If disease of the heart, kidneys or lungs co-exists special care should be taken. Before starting the injection and during the course of treatment the urine should be examined frequently for the presence of albumin.

CHAPTER XIV

MODE OF ACTION OF ANTIMONY COMPOUNDS

The mechanism of curative action of antimony compounds in leishmaniasis and bilharziasis is not understood. The important factor in the treatment of all protozoal diseases is that when an attempt is made to exterminate these parasites in the tissues, what appears to take place is that the drug destroys the majority of the parasites. The body resistance then rises and the patient's own natural powers of resistance finally eradicate the residual infection. This is almost certainly the case in kala-azar, where not infrequently a patient at the conclusion of a course of treatment may still show a few leishmania in the film on spleen puncture, and yet remain in perfect health thereafter and be cured. The same appears to hold good for malaria and trypanosomiasis and probably for amebiasis also.

In vitro experiments show that tartar emetic has little action on the cultures of leishmania. The toxic effects are not increased by bringing it in contact with fresh animal tissues; the organic arsenicals such as salvarsan, neosalvarsan, etc., are ten times more lethal to leishmania *in vitro* and yet they are not effective in the disease. Antimony is evenly distributed in the body and is quickly excreted by the kidneys; it never attains such a high concentration as may be directly parasitocidal. The pentavalent compounds do not differ in this respect from the trivalent compounds, and after an injection most of the antimony is, as a rule, eliminated in 3 or 4 days. Voegtline and Smith (1920) consider that pentavalent organic antimony compounds are first reduced to the trivalent state before they become active. It is very probable that the antimony ion in some form constitutes the parasitocidal agent, but whether oxidation or reduction occurs forming new compounds, or whether some protein compounds are formed in the serum, is difficult to say. The mechanism appears to be very similar to that of the action of mercury on the spirochaetes and it is probable that

antimony ions act by direct combination with the protoplasm of the parasites for which they appear to have a special affinity. The readiness with which antimony compounds dissociate into antimony ions is an important factor in their parasitotropic and organotropic properties. In mice infected with dourine, tartar emetic rapidly destroys the trypanosomes, since they disappear from the peripheral blood stream in 2 or 3 hours after the injection. With the pentavalent compounds, there is an interval of from one to two days before the trypanosomes disappear; but whether this latent period is due to a gradual reduction to a trivalent compound is not known. In human kala-azar there is also an interval which suggests that antimony in some way stimulates certain body functions, rendering the body environment detrimental for the development of leishmania. Chopra and Das Gupta (1927) showed that pentavalent compounds given intravenously stimulate the rhythmic contractions of the spleen and the liver and free Leishman-donovan bodies are found in the peripheral blood liberated by the rupture of endothelial cells. If the action of antimony was merely stimulatory better results would be obtained by repeated small doses. Clinical experience, however, shows that best results are obtained by pushing the treatment to the point of physiological limits.

Whatever may be the exact mode of action there is no doubt that the death rate in kala-azar has been reduced from 90 per cent. to 5 per cent. and that in Assam and Bengal, on account of extensive use of the antimonials, the disease is no longer in epidemic form and may in time completely disappear. Kolmer is of opinion that specific parasitocidal effects are enhanced or aided by certain non-specific protein reactions commonly observed after intravenous injections of proteins as well as after some metals in colloidal suspension. This is shown by the fact that slight leucocytosis is always noticed in rabbits after injection of antimony compounds, but whether any antibody is formed is not known.

CHAPTER XV

REMEDIES USED AGAINST TRYPANOSOMIASIS

Trypanosomiasis is a chronic disease of endemic areas in Central Africa due to *T. gambiense* or to *T. rhodesiense*, which are transmitted by the tse-tse fly. In man there are two stages of the disease. The first or hæmic stage and the second or the cerebral stage (sleeping sickness). The incubation period varies between two and twelve weeks and probably averages about six weeks. Trypanosomiasis is a very fatal disease. Although spontaneous recovery may take place in the early stages, it is believed that when the disease has arrived at the stage of sleeping sickness death is inevitable. Many areas in Africa have been completely depopulated through the ravages of the disease.

The causative organism. The trypanosomes are blood parasites which are widely distributed in animals, especially in big game in the countries in which these diseases occur. These animal hosts act as reservoirs of the trypanosomes which cause disease in man. *T. gambiense*, as seen in fresh blood, is an active wriggling organism, having a spindle-shaped body which is slightly compressed laterally and spirally twisted. There is no uniformity in the number of parasites present in the blood; sometimes they are fairly abundant, at other times, and in the same patient, it may be difficult or impossible, even after prolonged search, to find a single organism. In some instances they tend to recur cyclically at intervals of a week or more. On the whole, the parasites are most abundant in the blood during febrile attacks. At other times, trypanosomes may be found after triple centrifugalisation of citrated blood. The organisms are also found in the enlarged lymphatic glands, and in the cerebro-spinal fluid, as well as in that of the serous cavities.

Like the organisms of kala-azar, these parasites may be cultured on N. N. N. medium. They can usually be inoculated into most mammals including all the ordinary domestic and laboratory animals.

Germanin or Bayer 205 is a complex organic combination which was prepared in Germany in 1920; when used in veterinary medicine it is called *Naganol*. Its chemical composition was not revealed, but Fourneau (1923) prepared a substance of apparently identical action, named *Fourneau 309*

or *Moranyl*. This compound is believed to be identical with the German product. It is a derivative of the trypan-red class of dyes and chemically it is a symmetrical ureide of m-amino-benzoyl-m-amino-p-tolyl-l-naphthylamine-4 : 6 : 8-trisulphonate of sodium.

Germanin is a fine, white, flocculent powder which dissolves easily in physiological saline and cold water. The solution is faintly pink, odourless, slightly bitter in taste and neutral to litmus. The drug can be sterilised by heating in a water bath for 15 minutes, but solution in sterile water renders this unnecessary. Solutions can keep for some length of time, but it is advisable to give freshly prepared solutions. The drug both in a pure state and in solution should be kept away from light in amber-coloured bottles. A 10 per cent. solution is injected intravenously in man, and it is also said to be well borne subcutaneously, intramuscularly and orally. The intravenous route is preferable.

Pharmacology. Little is known about the pharmacology of this drug. It is slowly absorbed from the alimentary tract. In animals the drug has been found remarkably non-poisonous. The *dosis tolerata* has been estimated to be 160 times that of the *dosis therapeutica*. It could be given intrathecally to a dog in doses of 0.7 gm. without producing irritation or other ill effects. The drug is said to circulate in the blood for some time without losing its efficacy. It probably combines with the proteins of the serum and in this way is fixed and retained. Its presence can be detected in the internal organs for as long as 5 months after treatment. As the drug circulates in the body for weeks or months, it is not necessary to repeat it too often; it is doubtful if better results can be obtained by doing so. The trypanosomes develop a certain amount of resistance to it and it has toxic effects on the host. Its action on trypanosomes is said to be inhibitory to the multiplication of the parasites.

Effects on trypanosomes. It was found that the drug cured mice, rats, guinea-pigs and rabbits infected with *Trypanosoma brucei*, *T. equiperdum*, *T. equinum*, *T. gambiense* and *T. rhodesiense*. A dose of 0.0006 gm. or about 0.0024 gm. per kilogram of body weight cured mice, which become immune to reinoculation for a period of about three months. *T. cruzi* was unaffected but *T. venezuelense* (*T. evansi*) rapidly disappeared from the blood stream. Infections due to *Babesia mutans* or *B. bigemina* were unaffected. The proportion of the effective to the toxic dose (*i.e.*, the therapeutic index) in mice is 1 to 60, whilst in the case of atoxyl it is 1 : 2 (which means that twice the

effective dose would prove toxic). Fifty gm. given by the mouth to a goat, cured infection due to *T. rhodesiense*.

Toxicology. Duncan and Manson-Bahr (1923) found that in mice the drug in the kidneys produced extensive degeneration and exfoliation of the epithelium of the convoluted and other secreting tubules of the cortex; the straight tubules and excretory ducts appeared unaffected; some of the tubules contained hyaline casts and there were necrotic foci. The blood vessels were engorged, minute hæmorrhages occurred in the cortex and vessels showed perivascular round-cell infiltration. The liver and the lungs were engorged and fatty changes and focal necrosis occurred in the former; minute hæmorrhages also occurred in the lungs and in the brain. Marked anæmia was produced. In experiments in which the object is to produce sterilisation after a single dose, a great leucocytic reaction may be observed in relation to the sudden disappearance of parasites and death may result from shock. The drug circulates in the blood for days and even months, and consequently repeated doses have a cumulative effect. Regular examination of the urine is necessary and the appearance of a considerable amount of albumin is an indication to stop the treatment.

Therapeutic uses. Bayer 205 has been tried in sleeping sickness with encouraging results. The drug was given in human patients as early as 1922 with varying effects, the routine treatment being 1.0 gm. of the drug intravenously on the first, third and fifteenth days. In all cases in the first and second stages of the disease the improvement was well marked, but 96 cases out of a total of 150 whose blood was examined weekly, showed relapse. Trials by other workers also show that the first hopes entertained regarding the curative value of the drug were not fulfilled and Bayer 205 is distinctly less effective in trypanosomiasis when it has reached the second stage. Nevertheless, early cases due to *T. gambiense* respond so effectively to the action of the drug, as to suggest a permanent cure. Cases of chronic trypanosomiasis with changes in the cerebrospinal fluid show, as a rule, slight and only transient improvement. In some cases the cerebro-spinal fluid improves several months after the treatment is stopped and the condition may remain stationary. In the majority of cases the disease progresses to a fatal termination. In those cases in which the cerebrospinal fluid is normal and the infection is confined to glands and blood stream the drug is efficacious. The earlier the treatment is started the better

is the result. The drug undoubtedly produces disappearance of the trypanosomes from the peripheral blood and in this way the transmission of infection to the flies is prevented and spread of the disease is checked. Chesternan (1932) obtained promising results in trypanosomiasis with combined treatment; two or three large doses of Bayer 205, *i.e.*, 3 doses of 1.5 gm. for adults at 3 or 4 day intervals were given, followed by tryparsamide. A rest is then given for two weeks; particular care should however be taken to prevent visual troubles. Manson-Bahr (1932) obtained similar results with the combined tryparsamide and Bayer 205 therapy of sleeping sickness, the results depending more on the age of the infection than on the size of the doses or length of treatment. Bayer 205 is given up to a total of 3 gm. in the first week and subsequently tryparsamide is pushed in tolerated doses keeping a watch on the optic symptoms.

Dosage and method of administration. In human beings it is advisable to start with 0.5 gm. intravenously and if it is well borne, to give 1.0 to 1.5 gm. after 24 to 48 hours. The dose can be increased up to 3 gm. but it is not advisable to give such large doses more than once a week. One gramme is usually given weekly, in most cases repeated two or three times. Larger doses should only be given when the drug is well borne. Kleine gave it in 1.0 gm. doses at each injection on the 1st, 3rd and 15th day. In children proportionately smaller doses, *viz.*, 0.4 to 0.6 gm. are given, and in them the drug may be given into the jugular vein. More than five injections are not advisable. Low and Manson-Bahr (1922) gave 1 gm. weekly in 10 per cent. solution till 10 gm. were given; sometimes they gave a 20 per cent. solution, the amount being as much as 12 gm. within 14 days. Others recommend the first 3 doses at shorter intervals—every other day. As a rule, a 5 gm. course is considered sufficient on the 1st, 3rd and 5th day; if trypanosomes reappear after the 4th or 5th injection it is better to change to another drug. The drug cannot be given intrathecally, as it is likely to produce alarming symptoms. According to some weekly intervals between injections allow the trypanosomes to become resistant.

The trypanosomes do not disappear from the blood so rapidly as under tartar emetic, atoxyl, etc. As a rule, the blood is not free from the parasites till the second or third day after the injection. Frequent examinations of thick blood films or centrifugalisation of blood in citrated saline are necessary in cases of relapses to demonstrate the presence of the parasites. Sometimes isolated parasites appear after a few weeks but these disappear without further treatment. The best test for cure is to inject the infected blood into small experimental animals and see if the disease can be transmitted. Clinically, the action of the drug is apparent by disappearance of the glandular swellings in the neck, diminution in the size of the spleen, improvement of the blood picture, increase of body weight and general mental well-being.

In encephalitis lethargica or 'sleeping sickness' it has been tried but found to be quite useless. It has also been tried in diseases caused by spirochaetes, e.g., syphilis, yaws, etc., without success. Kala-azar and filariasis are said to be favourably influenced but it has no curative action on these conditions.

Toxic effects. The drug is not harmless and should be carefully handled. An erythematous rash sometimes appears, commencing on the forearms and spreading to the rest of the body. The eruption consists of central raised papules, rather patchy in distribution and finally it disappears by desquamation. Pruritus is a constant accompaniment, purulent conjunctivitis and stomatitis may occur. Albumin in the urine generally occurs after the second or third injection, and there may be blood and casts; anuria may occur. Symptoms of urinary irritation may subside after the termination of the course of treatment, but occasionally they persist. When patients are undergoing treatment a careful watch should be kept on the blood and the urine. The presence of albumin in the urine gives a warning although many authorities do not consider it a contra-indication to the use of the drug. Care, however, is indicated. Albuminuria may sometimes occur even after small doses. In many cases it disappears without leaving any permanent effects behind. Mayer, Kleine and others hold that albuminuria is

not necessarily an indication for the interruption of the treatment in patients whose kidneys are at other times normal. In some cases hæmolysis is produced. Optic troubles have not infrequently been observed. The Sleeping Sickness Commission in Portuguese West Africa in 1923 concluded, from their observations, that though Bayer 205 caused rapid disappearance of the trypanosomes, nephritis and in some cases amblyopia leading to complete amaurosis, militated against its general employment.

Prophylactic uses. Experiments conducted in Africa show that Bayer 205 and Fournau 309 have a definite prophylactic value. They afford protection for a long period, provided that the drugs are employed for the protection of healthy individuals. Healthy adults should be given two injections of 1.0 gm. each, younger people 0.5 gm., children 0.25 gm. and babies 0.1 gm. and each at an interval of 2 to 3 weeks. Sterilization of the blood of patients should also be carried out by treatment with atoxyl and other arsenicals. Recently, Lyndhurst Duke has shown that a single dose of 1 gm. of Bayer 205 given intravenously will protect a man for at least 113 days from infection by tsetse carrying cyclically *T. rhodesiense*. The administration of a second dose three weeks or so after the first enhances the protective effect of Bayer 205. Within certain limit the protective effect is directly proportional to the number of doses given, but the exact mode of action is not known. It is probable, though not definitely proved, that the protection conferred by Bayer 205 is greater against *T. rhodesiense* than against *T. gambiense*.

Mode of action. The mode of action of Bayer 205 is not properly understood. The drug produces no action on trypanosomes *in vitro*. After injection a trypanocidal substance can be demonstrated in the blood, milk, urine, etc., which may be the drug itself or a compound of it or some substance having no chemical relationship to it. A 1.0 per cent. solution of the drug lessens or abolishes the coagulation of blood serum by heat. Ehrlich considered the drug to be directly parasitocidal. Kleiger and Weitzmann (1926) injected cultures of trypanosomes together with Bayer 205 in experimental animals and found that they manifested an increased resistance which in some of them sufficed to ward off an attack. This increased power of resistance is not attributed to the protective power of the drug alone as the same phenomenon was observed in infected animals treated with Bayer 205. It is suggested that the

drug combines in some way with the trypanosome cell, producing a heterogenic antigen capable of stimulating the formation of specific antibodies. The action of the drug is not therefore purely parasitocidal; along with this property there may be an immunizing activity which completes the cure and affords an increased resistance in subsequent infection. Reiner and Koveskuty (1927) tried the drug in trypanosome infections of mice and concluded that Bayer 205 exerts its action directly on the parasites. But it did not alone kill the trypanosomes, hence the animals must have taken some part in the curative process.

Toxicity. Maximum tolerated dose in the mice is 0.01 gm. per 20 gm. body weight, in guinea-pigs 0.3 gm. per kilo. body weight; in rabbits 0.3 to 0.5 gm. per kilo. body weight.

Other Drugs in Trypanosomiasis

Arsenicals. Trypanosome infections were first treated with preparations of arsenic by Bruce (1895) and Lingard (1899) who employed them in animal trypanosomiasis. Later, Laveran and Mesnil (1902) used inorganic arsenic in an attempt to cure trypanosomiasis in laboratory animals.

Atoxyl (soamin). Atoxyl was employed by Koch (1907) in Africa in the treatment of sleeping sickness. The preliminary reports inspired great hopes, but later it was found that relapses frequently occurred, while optic atrophy was by no means uncommon. For details see the chapter on arsenic.

Tryparsamide. This drug was introduced for the treatment of trypanosomiasis by Drs. Brown and Pearce of the Rockefeller Institute. The preliminary experiments on laboratory animals were very encouraging, and further work in the Congo has strengthened the belief that in this drug, we possess a potent trypanocide. For further details, see the chapter on arsenic.

Fourneau 270 or sodium-4-acetyl amino-2-hydroxyphenyl-arsinate.

The action of this compound in sleeping sickness was first investigated by Ledentu and Daude (1926). Preliminary observations indicated that in the first stage the dose of 0.001 gm. per kilo. of body weight led to a disappearance of trypanosomes from the glands in 48 hours. Levaditi, Nicolan and Galloway (1926) have tested the prophylactic action of 270 when given by the mouth to rabbits subsequently infected with nagana. The drug has a prophylactic value but it is inferior to tryparsamide.

Fourneau 269 and 417. Two other compounds belonging to the above series were also used in trypanosomiasis. These can be given by the mouth, but the results have not been satisfactory.

Acetylarsan or oxy-acetylaminophenyl arsinate of diethylamine. This drug has been used by Van den Branden (1922) in the treatment of chronic trypanosomiasis. The results were not as satisfactory as with tryparsamide. For further details, see the chapter on arsenic.

Antimonials in trypanosomiasis. Antimony was first introduced in the treatment of trypanosomiasis by Plimner and Thompson (1908) who found that injections of potassium and sodium antimonyl tartrates cure infections of *T. brucei* or *T. evansi* in laboratory animals. It was formerly given intramuscularly but it caused great pain. It was then given intravenously. Excellent results have also been reported by the subcutaneous injection of antimony oxide suspended in equal parts of glycerine and water. This is practically painless.

Various organic preparations of antimony like antimosan have been tried from time to time without much success.

Bismuth in trypanosomiasis. Colloidal bismuth and a basic oxyaminophenyl arsinat of bismuth have been tried but the results are not encouraging.

Quinoline derivatives. Derivatives of anil- and styryl-quinolines have been tried in trypanosomiasis. The results are successful in rabbit trypanosomiasis. Clinical results have not been satisfactory.

SECTION III

REMEDIES USED AGAINST MALARIA

CHAPTER XVI

GENERAL CONSIDERATION

Malaria of all diseases is the greatest source of trouble to everyone living in tropical and subtropical climates. A résumé of its geographical distribution given by Rogers (1928) shows how widespread the disease is all over the world. During the Great War it caused the greatest loss of effective man-power, the largest invaliding and subsequent pension roll of any one disease. In India there are few malarial foci where it attains the same degree of virulence and intensity, as it does, for example, in Africa, Southern Italy and Greece, but the disease is so prevalent and widespread that India probably is one of the most malarious countries in the world. This is amply proved by statistics of the Public Health Commissioner with the Government of India. Malaria is still the principal cause of sickness among both the civil population and the army in India. A very large proportion of the troops, both British and Indian, suffer from it every year. Sir Andrew Balfour estimated the direct annual cost of sickness attributable to malaria in the British Empire to be roughly 52,000,000 to 62,000,000 pounds sterling and the annual world death-roll to be 2,000,000. The share of India might easily be half that amount. In India alone, according to James (1920) there are 1,300,000 deaths from endemic malaria in an ordinary year. Fortunately this is one of the few diseases against which true specific remedies are available. A thorough understanding of the action and uses of such remedies is therefore of vital importance to the medical profession in tropical and sub-tropical climates.

Incidence of malaria. The distribution of the three species of malaria parasites throughout the world has been studied in an exhaustive memoir by Knowles and Senior White (1930). This memoir includes

an analysis of all the available literature for the first thirty years of the present century and of a wealth of unpublished information with regard to India. Their main conclusions are:—The distribution of malaria in general throughout the world is limited in north and south hemispheres by the summer mean isotherms of 60°F.; the distribution of *P. falciparum* throughout the world is limited in both hemispheres by the mean summer isotherms of 70°F.; the distribution of *P. malariae* throughout the world shows a most curious and patchy distribution, suggesting that this is a dying species. The parasite findings both in peace and war differ as between military and civilian populations for reasons given. Mixed infections are relatively common, and constitute some 3.7 per cent. (or more) of the world. The relative gametocyte output for the three species is for *P. vivax* 21 per cent., *P. malariae* 45 per cent., *P. falciparum* 19 per cent., but, owing to the tremendously heavy production of merozoites by schizogony in the last named species, it is the one associated with epidemic malaria. In India (at least) the maximum output of gametocytes by *P. falciparum* appears to occur after the close of the transmission season, and this may be a very important factor in checking epidemics.

In England malaria existed in the low-lying countries. In France, Germany and Holland benign tertian infection exists, the carrier being *A. maculipennis*. In Macedonia both benign tertian (*P. vivax*) and malignant tertian (*P. falciparum*) forms exist and severe epidemics are known to occur. In Russia, Siberia, Albania and Palestine highly malarious areas are in existence. In India *A. culicifacies* and *A. stephensi* are the most important carriers. And in the Malay States *A. maculatus*, *A. funestus*, *A. aconitus* carry infections and *A. listoni* and *A. minimus* are associated with malignant tertian infections. Recently *A. ludlowi* has also been reported in India. *A. ludlowi* is the chief vector in the Dutch East Indies, Philippines, New Guinea, Africa, Algeria and Egypt. In South America (Brazil and Argentine) malaria is prevalent, the carriers being *A. tarsimaculatus* and *A. argyritarsis*.

Epidemiology. The main factors favouring high prevalence in the Punjab according to Gill (1923) are:—(1) The high relative humidity resulting from heavy rainfall in July and August; (2) A low spleen rate, indicating absence of temporary immunity due to recent attacks of malaria. (3) Economic distress and high price of food. (4) The occurrence in previous years of outbreaks of malaria. Such factors also play a part in other places. The necessity of a mean temperature of about 60°F. to enable malaria to be prevalent has been appreciated. This mean temperature must be maintained for sixteen days to allow full development of *P. vivax*, while in Macedonia a higher temperature is necessary for development of *P. falciparum*. Elevation and consequent low temperature limit the prevalence of the disease. In Kashmir at elevations of 6,000 to 8,000 feet, *A. maculipennis*, *A. fuliginosus* and *A. willmori*

are present in abundance, but no malaria exists because the temperature is not high enough for the parasites to develop.

Species and varieties of malarial parasites. Very few authorities now doubt the existence of three species, i.e., *P. vivax* (benign tertian), *P. falciparum* (malignant tertian) and *P. malariae* (quartan). Recently, *P. ovale* has also been described. There is a tendency to further subdivide these recognised species into minor varieties. The plurality view has been greatly strengthened lately by thousands of inoculations carried out in the treatment of G. P. I. and other nervous diseases. Cultures of the parasites have furnished additional evidence. The question of further subdivisions of the three primary types is more difficult though a quotidian variety of the sub-tertian has been recognised by some. Stephens has described *P. tenue*. Marchoux (1925) suggested that each of the three recognised species of malarial parasites exhibits different races with varying geographical distribution and morphology. The protozoologists are generally against the parthenogenesis theory of Schaudinn, and Ross's view that relapses are brought about by the spores of the asexual schizonts, which during latency are too small in number to be detected by the most careful microscopical examinations of the blood, furnishes a simple and likely explanation. Sinton has shown that parasites may be present in less than 1 c.mm. of blood, and yet may not be detected except by cultural method. The view that plasmodia are attached to the surface of the red blood corpuscle and not within it is supported by a number of workers. The ratio of crescents present is usually one male to two or more females.

Duration of infection in mosquitoes. The question as to how long anophelines once infected with malaria can remain infective to man has also been worked out by inoculation experiments. Infection could be produced by bites of *A. punctipennis* up to 55 days after feeding on crescents, and sporozoites were found in it.

Methods for studying the action of anti-malarial remedies. It will not be out of place to mention here the method by which the efficacy of the various antimalarial remedies is tested. Many observations recorded in the subsequent sections have been drawn as a result of these experiments.

1. Tests on the parasites of avian malaria—Type 'Proteosoma'.

These tests were primarily discovered by Copanaris, the brothers Sergeant, Giemsa and Marks, and were established as a routine laboratory practice by Roehl, who adopted the procedure of administering drugs to birds through an oesophageal tube passed into the stomach. The test consists in inoculating intraperitoneally a small quantity of blood from the bird which is being tested, into another bird of the same species. If the inoculated bird does not show parasites within a month, a second bird is inoculated in the same way. Canaries which have

passed the isodiagnostic test are infected with a known species of bird malaria (usually *Plasmodium relictum*, Grassi and Feletti) by direct blood inoculation, intramuscularly or intraperitoneally. The blood used for infecting the birds is taken when the parasites have reached their maximum number. It may be injected whole or diluted with physiological or citrate saline solution (one drop of blood in two drops of citrate solution). Four hours after infection, treatment with the drug to be tested is begun, and is continued daily for six days. The drug is administered through an oropharyngeal tube into the stomach, the usual dose being 1 c.cm. of a solution of known strength per 20 grammes body weight of the bird.

After ascertaining the maximum strength of the solution which the bird is able to tolerate in the dose given, a series of experiments is made to ascertain whether this strength of the drug causes delay in the appearance of parasites in the peripheral blood, and, if so, what further dilutions also cause a distinct delaying effect. The period of delay is ascertained by examining thin blood-films every day, the first day on which parasites can be found being compared with the first day on which they can be found in untreated control birds. In the control birds the parasites generally appear on the fifth day after infection. A drug is not considered to have a distinct therapeutic effect unless the delay in the appearance of parasites in the blood of treated birds is at least to the tenth day.

The birds used, should, whenever possible, be obtained from a country where natural infection with avian malaria parasites does not occur. When it cannot be guaranteed that the birds are free from previous infection, each bird should be examined prior to its inclusion in the series. It may be necessary to inoculate a specimen of blood into another bird to prove freedom from infection.

The test is used chiefly for the purpose of making a preliminary selection of those drugs which give an indication that they may be worthy of further study, from the numerous preparations which are submitted for examination.

2. Tests on the parasites of avian malaria—Type 'Halteridium.'

As long ago as 1906 the brothers Sargent showed that quinine has no curative action against parasites of the type 'halteridium' (*Hæmoproteus columbæ*), which occur naturally in pigeons and other birds. Since 1908 it has been the practice to try the effect of other drugs on these parasites as well as on those of the type 'proteosoma.' The species of parasite commonly used is *Hæmoproteus orientalis* which occurs as a natural infection in rice finches from Java and some other Eastern countries. It is a parasite of which only the gametocytes (male and female) can be found in the peripheral blood, the vegetative non-sexual cycle being passed in the endothelial cells of the lungs, the liver and other internal organs. Thus the object of therapeutic

tests with this parasite is chiefly to ascertain whether the drug to be tested has a gametocidal action. For this purpose one selects two or three naturally infected finches, and after having made a daily count of the parasites during a short period (four or five days), one treats the bird with the drug in the same way as in trials on 'proteosoma' parasites of canaries. The effect of the drug is observed by noting whether the parasites disappear or are greatly diminished in numbers as a result of the treatment.

3. *Tests on the malarial parasites of monkeys.*

It has recently been found that several varieties of malarial parasites which occur naturally in monkeys in the Far East and in Africa can be utilised for experimentally controlled therapeutic tests of antimalarial remedies. In particular, it has been found that a species of malaria parasite occurring naturally in monkeys of the species *Silenus irus*, when transferred by blood inoculation to *Silenus rhesus* or *sinicus* causes an acute infection which, when untreated, invariably ends fatally, but when treated with quinine, is cured or can be maintained at a low parasite level for months. In India, in the Malay States and in England, a beginning has been made in the application of this finding, to the practical purposes of therapeutic tests, and already results of a few carefully controlled trials with atebirin in comparison with quinine have been reported. The ability to work on the subject with monkeys as well as with birds is a noteworthy addition to the means at our disposal for evaluating the relative efficacy of antimalarial remedies.

4. *Therapeutic tests on human malaria induced intentionally.*

Since the introduction of malariatherapy, it has become possible to study the therapeutics of the disease under controlled conditions and to devise some useful tests for ascertaining the efficacy of preparations for prophylactic and curative purposes. It is to be understood, of course, that in all therapeutic tests on induced malaria, every endeavour should be made to imitate natural conditions as closely as possible. An essential condition is that the patients must be infected in the natural way by the bites of infected mosquitoes and not by the direct inoculation of malarial blood.

5. *Tests on human malaria contracted in the field.*

In general, the only test which can be conducted on patients who contract their infection in the field is a test of the immediate therapeutic value of a short course of the drug to be tested in comparison with the immediate therapeutic value of the same course with quinine.

6. *Microscopical study of the parasites in cases treated with a specific remedy.*

Diagnosis should be made by blood examination, thick films being preferred, as the parasites are more readily found by this means.

A thin film should also be examined to determine the species of the parasite. Injection of provocatives to bring the parasites into the peripheral blood stream has been advocated. Differential leucocyte counts have proved to be of very little value; a complement fixation test has been worked out but it is not satisfactory. The culture method is certain. Given a competent observer, examination of 100 fields of a thin film plus a reasonably careful examination of a thick film will enable a positive diagnosis to be made in 95 per cent. of all cases of developed malaria; but will only discover 67 per cent. of the cases of mixed infection. Whereas benign tertian infections tend to chronicity and relapses, and quartan infections to even greater chronicity with but few febrile manifestations, a preliminary study of untreated cases of malignant tertian malaria shows that infection usually does not persist in the individual in the absence of repeated fresh mosquito-borne infections.

Splenic index. The spleen rate is a simple and rapid method of estimating the degree of malaria in an affected area and gives results closely parallel to the more laboriously ascertained parasite index.

STUDY OF CURES

I. Natural cures. The life of a parasite depends on the life of the host, if the host dies millions of parasites which are living in it die also. There is a tendency in chronic protozoal infections for a condition of balanced equilibrium to be reached between the patient's power of resistance and the parasitic invasion. This condition one may term 'immunity' or better 'tolerance.' Hence their rate of multiplication is decreased by the formation of non-multiplying forms (gametocytes) from merozoites or asexual cycle. In untreated cases of malignant tertian infection, the fever subsides as soon as gametocytes alone are present in the blood. Thus a patient suffering from malaria is, after a fairly long period, cured of the disease without any treatment, provided, of course, he does not get reinfection during this time. Patients who leave the tropics are generally completely cured in about two years, though here and there one comes across with cases which persist for five years or more. Natural cures are partially brought about by excessive gametocyte formation which, so to say, converts the asexual cycle to non-multiplying gametocytes. Another factor also comes into play, especially when the patient has resided in a non-malarious district for a long time, and that

is senility of the gametocytes and their death from senile decay. It has been demonstrated that when the asexual cycle of *P. falciparum* is destroyed, for example, by quinine, gametocytes still occur in the peripheral blood; the sexual forms are gradually destroyed, though no further treatment is given (gametocytes can only multiply in the stomach of the mosquito).

II. **Artificial cures.** These are produced by the administration of certain antimalarial remedies, which act by destroying the asexual parasites, but have less effect on the gametocytes. The important factors concerned in these artificial cures are:-

(1) *The rate of parasite multiplication.*—It is known that the subtertian parasite multiplies at the rate of 24-32 merozoites in 48 hours, and according to Acton, is most influenced by quinine, while the benign tertian parasite forms 16 to 24 merozoites in 48 hours and is not so easily destroyed by quinine. A single *P. vivax* produces 24 new parasites in 48 hours, and at this rate of multiplication it can produce 250,000,000 descendants in fourteen days, a number which would produce about fifty parasites per c.mm. of blood. This is a number which can be detected microscopically but which will not give rise to fever. The next generation however will produce sufficient parasites to cause fever. A remedy which kills 96 per cent. of the parasites of the benign tertian form in 48 hours will not cure the disease, for it will only prevent the multiplication of parasites and will not reduce their number. As a matter of fact the rate of multiplication of parasites is somewhat less than that indicated above, because as soon as the multiplication of the parasites is checked, sexual forms appear, and since those can only reproduce in the body of the mosquitoes, they are inactive as far as the human body is concerned. That the difference in the rate of multiplication is not the only factor concerned is evident from the fact that the quartan parasite has the slowest rate of multiplication, i.e., 6 to 12 merozoites in 72 hours yet it is the most refractory to quinine.

(2) *Rate of parasite destruction.*—The percentage of each brood of parasites destroyed by continuous administration of antimalarial drugs is the other important factor. According to Ross, a man of average weight

(10 stones) has about 3,000,000 cubic millimetres of blood and allowing for 5,000,000 red blood corpuscles in each c.mm., there will be 15,000,000,000,000 red blood corpuscles present in the body. If there is one parasite per c.mm. of blood, it means 3,000,000 in the body. The lowest number of asexual parasites causing fever has been calculated to be about 100 per c.mm., *i.e.*, 300,000,000 parasites in the total quantity of blood. In severe infections of malignant tertian type the number of parasites is considerably higher, as many as 12 per cent. or more of the red blood corpuscles being infected. When the number of parasites falls below 300,000,000 they produce little or no symptoms—'parasitic relapse'. Theoretically a single parasite would in three weeks' time multiply sufficiently to produce fever, and therefore, to effect a cure every parasite must be destroyed. It is also known that in latent malaria, a large number of parasites can exist and multiply in the body without producing any apparent symptoms and any condition which lowers the vitality of the host, *e.g.*, unfavourable climate, fatigue, etc., tends to convert the latent into an active disease.

As regards the rate of destruction, it is known that a single dose of any of these drugs is not sufficient to effect a cure, but a series of doses has to be given. It has been shown that a large dose of quinine is cast out of the body rapidly, the tissues in this way protect themselves against the foreign chemical introduced into the body. The parasites in the host are not like fishes in a bowl which can be destroyed by mixing a single dose of poison with water. Many of them make good their escape and the drugs have therefore to be given in repeated doses daily, and continued for some time to keep down the parasites and produce a cure. These facts lead us to conclude that the rate of destruction must be below 100 per cent. The rate of destruction of the parasites, in order to produce a cure, has been calculated mathematically and found to be over 98 per cent. of each generation. It is well known that quinine causes a rapid amelioration of symptoms in all types of fever, and parasites also disappear from the peripheral blood. This effect is probably due to reduction of parasites from over 300,000,000 (febrile stage) to below that number (afebrile stage). Ross found

that 8 grains of quinine daily sufficed almost invariably to improve symptoms greatly while it was being taken, but it failed to produce complete cure even after 6 weeks' administration. Acton found the cure rate in benign tertian infection to be 20 per cent. after one month's treatment with quinine.

1. **Phases of artificial cure.** In the production of artificial cures, *i.e.*, those produced by drugs, several facts have to be taken into consideration.

- (A) The immediate and relative effect of the remedy used.
- (B) Partial cures or relapses.
- (C) Complete cures or sterilisation.

(A) **The immediate effects.** The parasitocidal effect is studied by noting the rapidity with which the asexual forms disappear from the peripheral blood and symptoms are relieved. Too much importance cannot however be attached to the picture presented by the peripheral blood as this gives little indication of what is brewing in the deep-seated foci. The curative effect, according to Acton, varies with the alkaloids used and species of parasite present. In malignant tertian infection schizonts become adhesive and form clumps and so block the smaller vessels of the brain and intestines, giving rise to pernicious symptoms. When quinine is given the trophozoites disappear within 24 hours after the first dose; gametocytes are not affected at all, as they have been found to exist for as long as 40 days after commencing treatment, and they are still able to undergo sexual reproduction in the stomach of anophelines. It has been demonstrated that if the asexual cycle is destroyed and the patient is put on ordinary tonic treatment (with no quinine whatever) gametocytes that are present either die of senility within a few weeks or are destroyed by the cells of the body, the patient undergoing a complete cure.

In benign tertian infections the asexual cycle takes place in the peripheral circulation and when quinine is given the young trophozoites disappear, within 24 hours after the first dose. The older trophozoites and the developing schizonts are not so easily affected, as they can be seen up to 48 hours (because sporulation is not completely prevented, and a slight attack of fever is often observed on the third day). The gametocytes disappear from the blood in 4 to 5 days, showing that they are less resistant to quinine than malignant tertian gametocytes.

The method of administration is an important factor in the rapidity of cure; the intravenous method is believed to be the most rapid in action and next come the intramuscular and the oral routes. As regards the different alkaloids of cinchona bark, the amorphous alkaloids which go by the name of quinoidine, have little effect, while the crystallisable alkaloids are all effective. If during the course of treatment parasites

reappear, it is certain that either the patient is avoiding treatment, or the interval between doses is too long or the alkaloid is not being absorbed.

(B) *Partial cures and relapses.* The destruction of the asexual cycle by the cinchona alkaloids is a gradual process of fractional destruction and it is obvious that one single dose or a few doses given at short periods do not suffice to effect a cure. As it is impossible to find out the exact time of liberation of each young brood, the ideal plan will be to give a continuous treatment long enough to affect many generations of the parasites (5 to 6 weeks to destroy 10 to 15 generations). Relapses in benign tertian infections cannot be attributed to insufficiency of quinine treatment, as in some of Acton's experiments this was carried on from 3 to 5½ months and in spite of this 50 per cent. relapsed. After the War there was a great outcry against the use of quinine in malaria because it failed to cure many cases. These observations were inconclusive and there were many sources of error. Quinine, if properly administered, will rapidly relieve the symptoms due to malarial parasites and if properly followed up, will prevent the parasite from causing death or serious damage to the patient. In spite of all the precautions, however, a permanent cure may not be obtained and relapses may occur. What then is the explanation of these relapses? The following possible explanations have been suggested regarding the escape of the parasites from destruction:—

(1) *Production of quinine-resistant forms.* Against this view is the fact that if quinine is properly administered in adequate doses, it causes immediate disappearance of the asexual parasites from the blood. It has often been stated that the first attack is more easily cured than subsequent ones and this has been proved by James' experiments with induced malaria. MacGilchrist (1915) in 149 cases in the Presidency goal found no cases of 'quinine-fastness' or even 'relative fastness' on the analogy with atoxyl in trypanosomiasis. The brothers Sargent (1921) carefully investigated the subject in the treatment of canaries infected with *Plasmodium relictum* and have proved this resistance to be of very rare occurrence. Acton and his colleagues in Dagshaki put a large batch of men on quinine treatment, and as they relapsed, repeated the treatment by giving a complete course of quinine again. They found that the cure percentage remained constant, i.e., 20 per cent. from the first to the fifth course of treatment. It is obvious that if the resistance of either the parasites or the host had altered, they would certainly have not become quinine resistant; they disappeared from the peripheral blood after quinine administration, in as short a time with the fifth relapse as with the first. Investigations by Fletcher (1923) showed that the alleged resistance to quinine in many of the cases during the Great War was apparent and not real, and that often it was due to quinine not being swallowed. The drug also may be adulterated. In any case if quinine resistant cases occur they are so few that if scrupulous care is taken

in the details of the treatment they may be ignored altogether. Quinine fastness or resistance of a particular strain of parasite cannot therefore be accepted as a cause of relapse. What, then, is the cause of relapses after quinine treatment? The parasites may take up their abode in the capillaries of the internal organs or in areas where body fluids do not freely reach them, or the patient's powers of resisting the infection (immunity) may not be stimulated.

The existence of back-waters, such as the spleen and the bone marrow, where owing to adsorption of the alkaloids by the tissues, quinine does not penetrate and parasites can go on multiplying, has been held as one of the causes. Recent studies have shown that it is in the finest capillaries of the grey matter of the brain and in the reticulated sinuses of the spleen and bone marrow that segmentation takes place and asexual parasites chiefly congregate. Some evidence has also been produced to show that in the blood-vascular system there are regions which are kept almost free from quinine throughout the period of quinine treatment. But it has been pointed out that in malignant tertian infections, schizogony occurs in the deep-seated areas, but in spite of this quinine is quite effective and acts as a specific, while in benign tertian where schizogony occurs in the peripheral blood it gives a lower cure rate.

(2) *Failure of quinine due to new species of parasites.* The opinion of protozoologists is against this view. The profound difference in the virulence between ordinary endemic malaria and malaria in epidemic form was thought to be due to different varieties of parasites, but Wenyon (1921) who examined countless blood films showed that the parasites were the same in both cases.

(3) *Failure due to non-absorption of quinine.* Failure due to non-absorption of quinine owing to catarrhal conditions and inflammation of the gastro-intestinal tract has been assigned as one of the causes. Observations show that quinine, as a rule, is readily absorbed from the gut even under such conditions. This can be demonstrated by testing the urine with Meyer's reagent.

It will be seen from the above that no satisfactory explanation is forthcoming and all that can be said is that relapses are due to incomplete destruction of the asexual cycle by the cinchona alkaloids. If all preliminary infections were really cured the incidence of malaria would diminish. Statistics of the Indian Army show that only 23.5 per cent. of the cases coming under treatment in endemic malarial areas are primary infections, while 76.5 per cent. are relapses and reinfections. If reinfections are prevented and quinine treatment is thorough, the percentage of relapses is diminished.

It has also been pointed out that relapses are much more common in cases of benign tertian than in malignant tertian. The question of individual resistance of the patient is important, as some persons acquire

malaria much more readily than others, and this factor also plays an important part in the quinine treatment of malaria. Proper treatment with cinchona alkaloids appears to be a very potent preventive measure. In relapsing cases, all predisposing causes, e.g., excesses of any kind, fatigue, exposure to heat and cold, should be avoided. Transfer to a non-malarial area such as a hill station is advised for persistent cases.

(C) **Complete cure or sterilisation.** This can be brought about in three possible ways:—

(1) *Response of the defensive mechanism of the body.* The effects of the alkaloids on the tissue cells of the host, making the erythrocytes noxious, causing the phagocytes to destroy the parasites or by the formation of antibodies.

(2) *Selective action of the alkaloids on merozoites in the blood.* It has however been found that large doses of quinine given during the cold stage have no greater beneficial action than when given at any other time. It has also been shown that high concentrations of quinine in plasma, though they give rise to symptoms of cinchonism, do not produce a cure more easily.

(3) *Selective parasitocidal action of different alkaloids.* Acton (1922) showed that although all crystallisable alkaloids affect both tertian and subtertian forms of parasites, quinine and cinchonidine (laevo-rotatory) appear to have a specially marked action on the malignant tertian parasites while cinchonine and quinidine (dextro-rotatory) have more powerful action on the benign tertian forms. He suggested that the efficacy of quinine against malignant tertian parasites is due to the fact that they sporulate in the mesenteric vessels, where quinine is present in greatest concentration, while the benign tertian and the quartan parasites are found in the peripheral blood stream where the concentration of quinine is much lower. Some other workers have produced evidence to show that quinine is more potent against the schizonts of *P. falciparum* than against those of *P. vivax*, whereas for the gametocytes the condition is reversed. The reaction of quartan malaria to quinine is again different and in this form it gives the most unsatisfactory results, whereas, quinidine is thought to be more effective in these cases. The Medical Research Council Report No. 96 (1925) does not bear out a preferential action of quinidine on benign tertian or of quinine on the sub-tertian infection.

CHAPTER XVII

THE CINCHONA ALKALOIDS

The Cinchona alkaloids occur in the various species of two rubiaceous genera, *Cinchona* and *Remijia*, which are indigenous to the eastern slopes of the Andes in South America between the latitudes 10°N and 20°S. *Cinchona* comprises about forty species of evergreen shrubs or trees, which grow isolated or in small clumps in dense forests. The average height at which they flourish is an altitude of 3,000 feet to 10,000 feet above the sea level. Some of the species are found as high as 11,000 while others as low as 2,500 feet. The trees may reach the height of 80 feet and are valued for their bark, which contains certain potent alkaloids.

All the evidence goes to show that although the natives of those parts suffered from tertian ague, they did not know the febrifuge properties of the bark. They believed it to be heating and therefore unfit for use in fever. Markham who visited America to obtain seeds in 1880 testifies to the fact that the wallets of the native doctors never contained cinchona bark. It is probable that the Jesuit missionaries were the first to discover the virtues of cinchona bark. In 1630 Don Juan Lopez de Cannizares, Spanish Corregidor of Loxa, was cured of an intermittent fever by the use of this bark. In 1638 the Countess of Cinchon, whose husband was viceroy of Peru, was stricken with intermittent fever which refused to yield to any of the known remedies. The Corregidor of Loxa sent the viceroy some bark with the assurance that it would cure the Countess. She tried it with happy results and the bark was also tested on many patients. In 1640, on her return to Madrid, the Countess brought a quantity of the bark with her. It was used in England by Robert Talbor, a physician, in 1655 as a secret remedy. With this he cured the Dauphin of France and Louis XIV who purchased the secret for 2000 louis d'or and at the same time granted him a life pension of 2000 francs. When Talbor died in 1681, Louis ordered the publication of his method of curing tertian and quartan ague.

The reputation of the bark as a cure for ague was not maintained for long as a good deal of the bark imported was not cinchona bark at all. Many physicians found the remedy useless and controversies arose as to its value. In spite of these failures the isolation of quinine by Pelletier in 1820 created a fresh demand for it. The use of the bark

had become so extensive that fears were entertained that the supply from South America would be exhausted. Attempts were then made to transplant some of the species to other countries, and in 1852 the Netherlands Government determined to attempt the transfer of cinchona from South America to Java in order to cultivate it in regular plantations. For this purpose the botanist, Justus Charles Hasskarl, went to South America and remained there till 1854. He succeeded in collecting live plants and the seeds of several varieties, and from these the plantations were started. The British expedition was sent to South America under the leadership of Sir Clements R. Markham and plantations were started in India (in the Nilgiris and the Palnai Hills of Travancore) in 1860 and in Ceylon (Hakgala) in 1861. As early as 1866 there were more than one and half million of cinchona plants in the Nilgiri Hills, the species growing best being *C. officinalis*. Plantations were also established in the Himalayas, British Sikkim near Darjeeling and in the Karen Hills in Burma. The species growing best there were *C. succirubra* and *C. calisaya*.

Of the large number of species and sub-species only a few yields commercially valuable barks. They are :—

- | | | | |
|------|--|--|------------------------------|
| I. | <i>C. officinalis</i> var. | $\left. \begin{array}{l} \textit{condaminea} \\ \textit{bonplandiana} \\ \textit{crispa} \end{array} \right\}$ | yielding crown barks. |
| II. | <i>C. succirubra</i> (Pavon), yielding red bark. | | |
| | <i>C. pitayensis</i> , etc. | | |
| III. | <i>C. lancifolia</i> | $\left. \begin{array}{l} \\ \\ \end{array} \right\}$ | yielding Columbian red bark. |
| | <i>C. cordifolia</i> | | |
| IV. | <i>C. nitida</i> | | |
| | <i>C. mircantha</i> | $\left. \begin{array}{l} \\ \\ \end{array} \right\}$ | yielding grey bark. |
| | <i>C. peruviana</i> | | |
| V. | <i>C. calisaya</i> yielding yellow bark. | | |

The successful transplantation of cinchona was followed by a period of researches and experiment to find the proper ways and means of propagating the new plants. In Java all the varieties were found to possess a low percentage of quinine with the sole exception of *C. officinalis*; this variety however did not grow very well. In 1865, a new variety of *Calisaya* seeds were received from Bolivia by a merchant named Charles Ledger. Ledger who was an Englishman sent his brother to London to sell the seeds to the British Government, but as negotiations were not successful and as he feared that the seeds would lose their germinating power, he sold them to the Netherlands Government. These seeds were planted in Java in 1865 and the first analysis of the bark in 1872 showed that of all the *Calisaya* varieties this specimen gave the highest yield of quinine, the average quinine content being 6 per cent., exceptional samples yielding from 10—12 per cent. The plantation of this variety was therefore taken up, and large plantations were started by the Government as well as by enterprising private individuals. Cinchona cultivation flourished in Java and at present about

9 to 10 million pounds of quinine are produced annually on an average, this may be estimated from the fact that about 90 per cent. of the quinine supply of the world comes from that island. The maximum content of the alkaloid occurs in trees between the ages of seven and eleven years. *C. succirubra* has proved the hardiest and most easily cultivated species, and it gives a high yield of total alkaloids (10 per cent.), in which quinidine and cinchonine content preponderates over that of quinine. In the hybrids, *C. officinalis* and *C. robusta* the total alkaloidal content is very large, and of late years the quinine yield has also considerably increased.

Cupressæ cortex contains both cupreine and quinine and is obtained from *Remijia pedunculata* and other species.

The therapeutic effects of cinchona bark are due to the alkaloids present; of these quinine is the best known, while quinidine, cinchonine and cinchonidine have been used to a comparatively less extent in medicine. The alkaloids are contained in the cellular tissue of the phloem. In the leaves they are only present in small quantities but larger quantities are found in the stem bark increasing from above downwards as the root is approached. The alkaloids exist in the bark in combination with cinchotannic acid and quinic acid. The former is oxidised by exposure to a red colouring matter which is present in large quantities in *C. succirubra*. The principal dried barks used for the production of quinine are :—*C. succirubra* (red cinchona bark), 1,000 gm of good bark yielding at least 50 gm. of total alkaloids containing 15 gm. of quinine sulphate; *C. calisaya* (yellow cinchona bark) which with the same amount of bark yields 60 gm. of total alkaloid containing 30 gm. of quinine sulphate; *C. officinalis* (crown or Loxa bark) containing 5 per cent. of total alkaloids, of which 3½ per cent. is quinine; the bark of *C. lancifolia* or Columbian bark contains about 2 per cent. of the alkaloids with only a small proportion of quinine.

The bark is usually collected by felling the trees or by 'capicing'. These methods are now largely employed in preference to other methods and the plantations are so arranged that every year a large area is matured and the trees are ready for cutting down. The trees yield the maximum amount of alkaloids when they are 6 to 9 years old and it is about this time that they are cut down.

The total production of quinine is about 600,000 kg. per annum manufactured in 14 different factories; it is doubtful if this amount is sufficient for the needs of the whole world. It is said that even the present production is in excess of the commercial demand, but it is also true that owing to its high price, millions of people suffering from malaria cannot get it.

Composition of Cinchona bark. Pelletier and Dumas in 1820 isolated quinine from the bark and Cunningham predicted

long ago that probably the bark contained other alkaloids as well. Further investigations have shown that as many as twenty alkaloids and probably more, the majority of which have been isolated by Hesse are present in the bark from various species. These are divided into crystallisable and amorphous. The bark in addition to these alkaloids contains certain acids, neutral principles, colouring matter and traces of a volatile oil, gum, starch and other vegetable matter. The ash 1 to 2 per cent. consists mainly of calcium and potassium carbonates and a little silica. The large amount of ash present in cinchona febrifuge is due to the fact that magnesium sulphate is added to the alkaloidal mass in order to make it more amorphous.

Extraction of Cinchona alkaloids. The bark is dried and ground to a fine powder mixed with slaked lime, which is passed through a sieve of 40 meshes to the linear inch, sufficient water being added to make it damp. The addition of lime makes the subsequent extraction of the alkaloids easier. The mixture is made into a thin paste with water and put into vats. Caustic soda and warm paraffin oil are then added and the vats heated to 170°F. with frequent stirring of their contents ; these are then allowed to settle when two layers form, the oil on the top containing the alkaloids and the exhausted bark below. The oil is decanted off and mixed with dilute sulphuric acid which dissolves all the alkaloids. The mixture on standing separates into two layers, the acid liquor containing all the alkaloids in solution. The alkaloids are then precipitated by adding caustic soda. The crude total alkaloids thus obtained, sometimes called cinchona febrifuge are further purified.

Cinchona Febrifuge. The cinchona febrifuge was first prepared in India in 1874 at the instance of Dr. J. F. de Vrij, who suggested the manufacture of a powder containing all cinchona alkaloids derived from *C. succirubra*. It was prepared by exhausting the powdered red bark with water acidulated with hydrochloric acid, precipitating the liquor with soda and drying the crude product. This continued to be the only product of the Indian factories until 1887 when quinine manufacture was started. In the meantime quinine began to be considered the only effective alkaloid in the treatment of malaria and there was a demand for barks containing a higher percentage of this alkaloid. The result was that cultivation of yellow bark from *C. calisaya*, *C. ledgeriana* and their hybrids, which contain higher proportions of quinine, was encouraged. About 1903 the scarcity of *C. succirubra* bark in India led to an alteration in the process of manufacture of cinchona febrifuge. This now consists of alkaloids which remain after the extraction of the quinine from the yellow bark, some quinine being

added to make it more or less similar in composition to the original cinchona febrifuge.

As met with generally, cinchona febrifuge appears to consist of any mixture of the bark extracts and by-products of quinine manufacture which makers wish to get rid of. Some of these mixtures are of excellent quality and contain a large percentage of the alkaloids, and are considered by many experienced physicians to be therapeutically as good as quinine; others are decidedly inferior and contain small proportions of the alkaloids. The following tables give the composition and the variations in the alkaloidal contents of different specimens which have been analysed.

ANALYSIS OF CINCHONA FEBRIFUGE

No.	Source of Samples.	Quinine per cent.	Cinchonidine per cent.	Quinidine per cent.	Cinchonine per cent.	Total crystalline alkaloid	Quinoidine (amorphous alkaloid) per cent.
1.	Dr. Vrij's analysis of Java febrifuge (1876)	2.9 to 22.2	24.0 to 60.4	2.8 to 5.4	18.0 to 54.0	..	0.4 to 21.0
2.	Cinchona febrifuge (total alkaloid of <i>C. succirubra</i>) ...	15.5	29.0	..	33.5	78.0	17.0
3.	Cinchona febrifuge from Mungpoo (Mac-Gilchrist 1914-15) ..	7.4	5.8	22.8	18.6	54.6	29.1
4.	Cinchona febrifuge Govt. of India (Gage 1922)	10.5	7.0	16.0	28.0	56.5	38.0
5.	Cinchona febrifuge tablet, Govt. of India (Howard 1918) ..	2.7	8.4	12.5	12.8	80.9	54.9
6.	Do.	8.0	21.0	4.5	21.0	54.5	80.0
7.	Cinchona febrifuge (Java) ...	5.8	12.2	8.7	20.0	46.7	41.8
8.	Do.	11.9	9.2	4.8	15.8	41.2	45.4
9.	Cinchona febrifuge (Quinetum), Europe.	8.5	7.0	8.6	28.8	52.4	44.7
10.	Cinchona febrifuge (Quinetum), used in League of Nations' clinical trial.	15.0	35.0	5.0	25.0	80.0	20.0

			CINCHONA FEBRIFUGE		Residual Alkaloids Indian
			Indian percentage	Javan percentage	
Quinine	7'40	11'5	3'0
Cinchonine	..		18'58	26'3	35'0
Quinidine	22'83	5'0	20'0
Cinchonidine	5'84	20'0	2'0
Total		..	54'65	62'8	60'0
Quinoidine	29'12	37'2	30'0
Water and ash	16'23	...	10'0

A perusal of the above results will show that the amount of the crystalline alkaloids having an antimalarial action present in the two brands of 'cinchona febrifuge,' as well as in the residual alkaloids, is sufficient to produce therapeutic effects. It will be seen also that 'cinchona febrifuge' has no fixed composition and is frequently adulterated. The 'cinchona febrifuge,' as issued from the Government factories in India, is mostly the residual alkaloid preparation from the bark of *C. ledgeriana* after most of the quinine has been removed.

Quinetum and Quininum. Another product of cinchona bark, similar to cinchona febrifuge, used in India is quinatum. According to some, it is a substance like cinchona febrifuge containing all the alkaloids, but only 15 per cent. of quinine and 5 per cent. of quinidine. According to others, it is a mixture of cinchona alkaloids as they occur in the bark of *C. succirubra* and consisting of sulphates of cinchonidine, cinchonine and quinidine with smaller quantities of the sulphates of quinine and amorphous bases. Some even say it is simply a mixture of amorphous bases of cinchona bark, the crystalline alkaloids having been previously removed. The confusion with regard to 'quinatum' has recently been disentangled by the Commission of Expert Malarialogists appointed by the League of Nations. The name 'quinatum' should be reserved for a preparation consisting of quinine, cinchonidine and cinchonine in equal parts. If this preparation is made by extracting those alkaloids from the bark of *Cinchona succirubra* (which usually contains them in approximately equal quantities), only a small addition of one or other of the crystalline alkaloids will be necessary in order to equalise the amount of each alkaloid in the preparation.

Quininum is an extract prepared according to a French formula. It contains all the constituents of the bark except the woody fibres.

and (2), that the distribution in space is the same about these atoms, and in all four cases is dextro-rotatory in total effect.

The deoxy-bases, obtained from cinchonine and quinidine and from cinchonidine and quinine are structurally identical, but differ in optical properties, the first pair being dextro- and the second pair laevo-rotatory. These deoxy-bases have the same general formula where R is $\text{C}_6\text{H}_8\text{N}$ for cinchonine and cinchonidine, and $\text{C}_9\text{H}_8(\text{OMe})\text{N}$ for quinine and quinidine, and carbon atom (4) is no longer asymmetric. It follows that the difference in optical activity in these bases, and therefore in the four alkaloids from which they are derived, depends on the arrangement of groups round carbon atom (3) and is different in sign in the two pairs.

It is thus possible to divide the cinchona alkaloids into two series, a dextrorotatory and a laevorotatory :—

Chemical Name	Natural Alkaloid	Corresponding hydroalkaloid
---------------	------------------	-----------------------------

Cinchonine Series—Dextrorotatory Alkaloids

Cinchonine	Cinchonine	Hydrocinchonine
Hydroxycinchonine	(Cupreidine—unknown)	Hydrocupreidine
Methoxycinchonine	Quinidine	Hydroquinidine

Cinchonidine Series—Laevorotatory Isomerides

Cinchonidine	Cinchonidine	Hydrocinchonidine
Hydroxycinchonidine	Cupreine	Hydrocupreine
Methoxycinchonidine	Quinine	Hydroquinine

Acton (1922) believes that the pharmacological properties of the two groups also show a divergence, which is dependent on three factors in the structure of the complex alkaloid molecule :—

I. The grouping of the quinuclidine system round the asymmetric atom (3). The dextrorotatory alkaloids are more powerful in their effects than the laevorotatory alkaloids of the cinchonidine series, as

shown by their toxicity to mice and to paramœcium, by their inhibitory action on enzymes, and by their effects on blood pressure and uterine muscle. The cinchonidine series act more powerfully as local anæsthetics.

II. The vinyl group ($\text{CH}=\text{CH}_2$) in the quinuclidine system. The natural alkaloids are rather more toxic to paramœcium than the hydroalkaloids. The latter are more toxic to mice, inhibit enzyme action, and cause a greater fall of blood pressure and greater uterine contraction than the natural alkaloids.

III. The group R in the quinoline ring. The higher members of both series of the hydroalkaloids are more toxic to mice, paramœcium, bacteria and leucocytes, and are more powerful local anæsthetics. Their action on the inhibition of enzymes, on blood pressure and uterine muscle is reduced.

Considerable interest in the past few years has been aroused by the modified cinchona alkaloids, for with hydrogenation of the vinyl group and replacement of the methoxyl group of quinine and quinidine by higher alkyloxy groups, the following compounds are produced. When the alkyloxy group is

- OCH_3 there is formed Methylhydrocupreine.
- OC_2H_5 there is formed Ethylhydrocupreine (Optochin).
- $\text{OC}(\text{CH}_3)_2$ there is formed *iso*-Propylhydrocupreine.
- $\text{OCH}_2\text{—C}(\text{CH}_3)_2$ there is formed *iso*-Butylhydrocupreine.
- $\text{OCH}_2\text{—CH}_2\text{—CH}(\text{CH}_3)_2$ there is formed *iso*-Amylhydrocupreine (Eukupin).
- $\text{O}(\text{CH}_2)_5\text{—CH}(\text{C}(\text{CH}_3)_2)$ there is formed *iso*-Octylhydrocupreine (Vuzin).

Optochin is highly toxic to the pneumococcus, vuzin to *Corynebacterium diphtheria*, while both eukupin and vuzin have been used as dressings for septic wounds and are said to be powerful anæsthetics. Although Izar and Nicosia (1914) have recommended the use of optochin in malaria, it is actually much less effective and far more toxic than quinine. The same is true of eukupin and vuzin.

CHAPTER XVII

PHARMACOLOGICAL ACTION OF CINCHONA ALKALOIDS

To comprehend the rationale of the therapeutic action of these alkaloids it is important to have a clear idea of their general pharmacological action. The type of action produced by quinine closely resembles that produced by the other alkaloids and it can be taken as a typical example of this group.

Action on protoplasm. Quinine occupies a peculiar position among the vegetable alkaloids. While most of the other alkaloids have a more or less cleanly defined point of attack in the body, and act on special tissues, quinine acts as a general protoplasmic poison which in sufficient concentrations destroys all cells, including those in which purely vegetative processes take place. Its action is specially marked on leucocytes, amœbæ and spermatozoa. The action generally begins with temporary stimulation of activity of the protoplasm, being quickly followed by inhibition of all vital processes and finally death. It has been shown that quinine, like saponins and proteins, tends to concentrate on the surface of solutions to such an extent as to form almost a rigid film (Ramsden). This interferes with the condensation of other substances at the surface and the catalytic phenomena, inorganic as well as organic, are hindered, resulting in diminished metabolism. The surface action is also demonstrated by the arrest of Brownian movement and there is a tendency to precipitate colloidal solutions such as proteins. Quinine may thus produce anaphylactoid phenomena. The quinine film probably decreases the permeability of the cell, thereby producing a narcotic action such as is seen on local application to nerve cells, muscle cells, etc. The inhibition of movements of the white blood cells, spermatozoa, infusoria, and ciliata, is probably due to the rigidity of the film formed. All these effects give this alkaloid the property of being a general protoplasmic poison. Its toxicity to vertebrates is however comparatively low; probably it is bound up or deposited in insoluble or harmless form in some of the tissues of the body.

Protozoa. If quinine is allowed to act on the undifferentiated protoplasm of such an organism as an amœba its action is quite characteristic. The metabolic processes in the cell are retarded and this affects not only the anabolism but katabolism also. Minute doses therefore merely produce slowing of the activities in the organisms, while large doses produce first paralysis and then death. Very dilute solutions such as 1 in 20,000 to 50,000 destroy amœbæ and paramœcia in a few hours

and some pathogenic protozoa, e.g., plasmodia. The protoplasm in amoebae becomes granular, spherical and in a few hours nothing but granular detritus remains; this action occurs in the plasmodia in presence of the merest traces of quinine. Mice given a few daily injections of 5 to 6 mgm. of quinine are said not to be infected with nagana, although these doses will not free the infected mice from the parasites. Dourine is not influenced but the incubation period of rabies is prolonged by large doses. Bass and Johns in 1912 first cultivated the malarial parasite. Bass later showed that 0.005 c cm of a 15 per cent. solution of quinine dihydrochloride corresponding to 2 gm. in the blood of a person weighing 150 lbs., killed *P. falciparum* in 5 to 29 hours. The activity of certain forms of non-pathogenic spirochaetae, amoebae, etc., is inhibited at first and finally stops. Certain protozoa are however not affected by quinine at all; salt water amoebae and spirochaetae of relapsing fever are able to live in a 1 in 200 solution.

Bacteria. The toxic action of quinine on the protoplasm endows it with bactericidal power but the action of the alkaloid on cocci and bacilli is somewhat varied. Its germicidal efficiency is considered to be about half that of phenol, whilst its antiseptic action approaches that of mercuric chloride. A dilution of 1 in 2,000 delays growth of bacteria and 1 in 800 inhibits the growth in fluids of organic matter and prevents lactic and butyric acid fermentation. The drug also retards the action of many unorganised ferments.

Some organisms are very sensitive to quinine and its derivatives while it has little or no action on others. Moulds are most resistant to it, in fact, they thrive in solution of quinine sulphate. About 0.5 per cent. is required to stop the growth of putrefactive bacteria and 2 per cent. to kill them. Typhoid bacilli cannot grow in 1 in 30,000 solution. Quinine has no direct influence on the course of most bacterial infections whether given by injection or otherwise, the pneumococcus being an exception in this respect. Both quinine and related alkaloids when used in sufficiently large doses early enough have been successful in controlling experimental pneumococcal infection in animal and pneumonia in man. Some of the newer derivatives of cinchona, for example the cupreines, exert a powerful bactericidal action on certain micro-organisms even in the presence of proteins, and at the same time have a relatively low toxicity for the body cells. This action as a rule increases as we go up the series from ethyl hydrocupreine to iso-octylhydrocupreine. Thus quinine in 1 in 1,000 concentrations, ethylhydrocupreine in 1 in 2,500 and iso-octylhydrocupreine or vuzin in 1 in 60,000 concentrations, will destroy *B. tetanus*. The same is true of streptococcus, staphylococcus and *B. diphtheria* with some reservations. Below is a table showing the relative bactericidal action of quinine derivatives on some micro-organisms (Dixon).

Bactericidal action of quinine derivatives

	Diph- theria bacillus	Tetanus bacillus	Strepto- coccus	Staphylo- coccus	Pneumo- coccus
Quinine Hydrochloride	1--100	1- 1,000	1- 1,000	1- 500	1- 2,000
Ethyl Hydrocupreine Hydrochloride (Optochin)	1- 400	1 2,500		1- 500	1 - 400,000
Isopropylhydrocupreine hydrochloride	1- 800	.	1--8,000	1-1,000	1-200,000
Isoamyl hydrocupreine hydrochloride (Eukupin)	1-2,000	1- 20,000	1-40,000	1-8,000	1-20,000
Heptyl hydrocupreine bihydrochloride ..	1-8,000			1-64,000	
Isooctyl hydrocupreine (Vuzin) ..	1-8,000	1--60,000	1-80,000	1-6,000	
Eucuprinotoxin ...			1-60,000	1- 52,000	

The corresponding series of cupreidine compounds have similar actions.

Ethyl hydrocupreine known under the trade name of Optochin has a very high degree of toxicity for the pneumococcus, 1 in 400,000 solution having a destructive effect on this organism *in vitro*; 1 in 800,000 solution in serum inhibits the growth of pneumococci. Strains of pneumococci and also streptococci are inhibited *in vitro* by 1 in 100,000 solution whereas meningococci and gonococci require a strength between 1 in 10,000 to 1 in 5,000. This selective action of the drug led to its trial in pneumococcal septicaemia produced in rats and guineapigs, but the results were not conclusive. To get a bactericidal action it was found necessary to give 0.024 gm. per kilo. body weight in 24 hours, and for an average man this will mean a dose of just over 1.5 gm. Doses of 20 to 25 grains in 24 hours render the blood toxic to pneumococci but such effects of quinine as contraction of the field of vision and amblyopia, which are met with in therapeutic doses, are much more marked in the case of ethyl hydrocupreine and even such small doses as 8 grains have produced optic atrophy with permanent blindness. Further trials of this drug in man were therefore not proceeded with. Doses of 0.5 gm. in the treatment of pneumonia caused total blindness in some individuals, while in others vision partly returned. Pathological changes in the retina consist of white patches of necrosis, narrowing of blood vessels and sclerosis, as evidenced by depigmented areas. A combination of injury to the optic nerve, the retina and the choroid appears to be a peculiarity

of this drug. Susceptibility to these effects varies in different individuals. Besides it should be remembered that when the infection is at its height, the toxins have already had time to affect the tissue cells and mere destruction of pneumococci will be of little value. Bactericidal tests on different types of pneumococci show that in dilutions of 1 to 2 millions, ethyl hydrocupreine hydrochloride (optochin) kills type 3 of this organism; quinine arsenate does the same in 1 in 200,000 to 1 in 100,000, quinine sulphate 1 in 200,000 to 1 in 20,000, quinine hydrochloride 1 in 200,000 to 1 in 100,000 dilutions. The inhibiting effect of quinine on the pneumococcus is even greater than its germicidal power. Quinine hydrochloride and dihydrobromide exert a marked neutralising action on the toxicity of pneumonic lung extracts, prophylactic injections prolonging the life of animals 5 days or more, after injection of one M.L.D. of the extract, while quinine and urea hydrochloride and optochin afford little or no protection. The protective value of antipneumococcic serum in animals has been shown to be increased by the simultaneous injection of optochin and to a lesser extent by other quinine compounds.

Iso-octyl-hydro-cupreine or vuzin. This compound was extensively employed by the Germans during the War for disinfecting suppurating gunshot wounds, owing to its remarkable bactericidal action on streptococci and tetanus bacilli in very high dilutions (1 in 80,000 and 1 in 60,000 respectively). It was used in strengths of 0.1 gm. in a litre of water and proved to be very efficacious. It is also effective against the micro-organisms responsible for gas gangrene. Iso-heptyl-hydrocupreine is especially destructive to staphylococci.

Iso-amylhydrocupreine (Eukupin) has been found to have a specific effect against vibrios and diphtheria bacilli. It has been tried in Vincent's angina, and it is useful in other forms of ulceration, e.g., Cachar or Naga sore. Both 'vuzin' and 'eukupin' are readily absorbed, but act more slowly than quinine when administered to man by the mouth.

The destruction of the micro-organisms is probably brought about by the combination of these alkaloids with the protoplasm of the bacteria, and their varying qualitative efficacy against different micro-organisms can be accounted for by the difference in their affinity for them. The bactericidal action of the alkyl derivatives of hydrocupreine is more or less similar to that of quinine, but they are much more toxic.

External action. Quinine solutions applied to the unbroken skin do not produce any disagreeable sensation. Rashes are however frequently produced in workers in quinine factories after prolonged exposure to the drug and certain local irritation is set up. Quinine and its salts are not absorbed by the intact skin except under the influence of an electric current. They are however taken up rapidly by the mucous membrane.

Alimentary system. When taken by the mouth quinine acts as a bitter, stimulates the gustatory apparatus and improves the appetite; the peptic glands are reflexly stimulated. In the stomach it is dissolved by the hydrochloric acid but it has no direct action on the flow of the gastric juice. Given by the mouth there is little difference between soluble and insoluble salts, as the alkaloid is converted into soluble hydrochloride and the less soluble salts are made more soluble by the gastric acid. Passing into the duodenum, it is usually absorbed rapidly. After absorption quinine circulates in the blood as quinine base. The absorption occurs mainly from the small intestine and it is rapid and complete. The largest amounts are absorbed during the first six hours after administration of a dose. Only a small amount is taken up from the stomach when it is given on a fasting stomach and in the form of a soluble salt; a relatively smaller amount is absorbed from the large intestine. Absorption is retarded if quinine is given with or soon after food. The soluble salts of the alkaloid are absorbed a little more quickly than the insoluble ones, for compounds like equinine and quinine tannate have first to be hydrolysed by the alkali of the duodenum before they are absorbed.

Ferments. Interference with the activity of ferments is a well-marked property of quinine and its inhibiting action on oxydases in the blood is well known. The acidification of shed blood is slowed. Freshly excised still-living kidneys, perfused with blood containing glycocoll convert benzoic acid into hippuric acid; if however minute traces of quinine are added to the blood this synthesis is prevented. It seems likely that the chief effect of quinine on the living organism is to restrict many of the normal chemical changes—synthesis, oxidation and decomposition and in this way to diminish the metabolism (Schmideberg). These effects are probably due to the paralysing action of quinine on the intracellular enzymes by whose aid the chemical changes are brought about. It is doubtful if the concentrations of quinine, in therapeutic doses, rise so high as to hinder action of oxydases in the body. All the metabolic processes in the body, whether of anabolic or katabolic nature, are decidedly inhibited and tissue waste and energy production are both retarded.

Various digestive enzymes are affected to varying extents according to the degree of concentration of the alkaloids. Acton (1921) studied the action of cinchona alkaloids on these enzymes *in vitro* and found that the activity of ptyalin, the starch digesting ferment of the saliva, was completely inhibited by the acid salts. As the digestion of starches is over in 10–30 minutes, no interference will result if the alkaloids are given half an hour after a meal. Peptic inhibition is more marked with the cinchonine series and the inhibition is less when the ferment first attacks the protein than when the protein is first acted upon by the alkaloids. On the tryptic digestion, quinidine has a more powerful

inhibiting action than quinine; the action of pepsin is retarded in the presence of a 1 in 5,000 solution of quinine or quinidine. The deduction of practical importance that can be made from these experiments is that, as the inhibition of peptic digestion is bound to lead to deficient peptone formation, the time of administration of these alkaloids in relation to meals is of the utmost importance. They should be administered when they least interfere with the activity of the digestive enzymes, that is about 1½ to 2½ hours after meals.

Circulatory system. *Action on the blood: Leucocytes.* If quinine is given intravenously in large doses to an animal, certain changes are noticed in the blood corpuscles. The leucocytes lose their amoeboid movements, become round and granular, diapedesis through the capillary walls ceases and the coagulation time of the blood is reduced. Even in very low concentrations (such as those occurring in the blood after administration of therapeutic doses of quinine) the movements of the leucocytes are inhibited and diapedesis is stopped. This can be demonstrated in the exposed mesentery of the frog. The number of white blood corpuscles in man is reduced to half the normal number per c.mm. of blood or even less, after administration of a dose which is 1/20,000 of the body weight, lymphocytes being chiefly affected. This leucopenia is often preceded by a preliminary leucocytosis in which chiefly the polymorphonuclears are concerned. For these reasons quinine is said to counteract inflammation and suppuration and is recommended in catarrh of the nasal passages.

Erythrocytes. On the erythrocytes, the acid salts of quinine have a decidedly hæmolytic action *in vitro*, and blackwater fever has been attributed by some to the toxic effects of quinine salts on the red blood cells. Rarely, ecchymosis may occur in the tissues after administration of quinine, probably from injury to the erythrocytes leading to the formation of thrombi, or from injury to the walls of the small vessels. The hæmoglobin shows a characteristic change with strong solutions of quinine. Neither acid hæmatin nor methæmoglobin is formed; uuzin has similar action.

It has already been stated that quinine circulates in the blood as quinine base. Acton has demonstrated that strong solutions of quinine and quinidine base such as 1 in 2000 in normal saline, produce no hæmolysis of washed red corpuscles *in vitro*, even after incubation for 24 hours. In the case of acid salts, such as the bisulphate, there is faint hæmolysis in 1 in 8000 solution, but none whatever in 1 in 11,000 dilution. Intravenous injections of strong solutions of acid salts are therefore highly undesirable and there is no doubt that rigors, which are sometimes observed after such injections, are due to the hæmolysis thus produced. As a matter of fact, injection of acid salts of quinine and other cinchona alkaloids, whether intravenous or intramuscular, is not justifiable from a physiological point of view, as those alkaloids circulate in the blood as bases. The acid salts are preferred

merely because they are soluble and therefore convenient for administration.

Blood pressure. The blood pressure is definitely lowered after intravenous injection and Acton has pointed out that this depression is much more marked with the dextro-rotatory cinchonine series, quiniidine being the worst offender in this respect. His experiments show that it causes a much bigger fall, the effects are more prolonged and therefore it should not be given by this route.

Action on the heart. The heart muscle is acted on in the same way as the other muscular tissue. Very small quantities accelerate the pulse and raise the blood pressure; large quantities produce the reverse effect, the action is directly on the motor apparatus of the heart and not on the nerves. The depression of the heart is no doubt responsible for the collapse produced by very large doses in patients suffering from fever. Quinine depresses isolated strips of the heart of a turtle. A frog's heart is weakened by 1 in 50,000 solution, and 1 in 5,000 stops the heart in diastole in a few minutes (large doses of digitalis stop the heart in systole). It is for this reason given in irritable conditions of the myocardium.

Quinine is considered by some authorities to be the greatest regulator in arrhythmia due to extra-systole including auricular fibrillation. It has been combined with digitalis in cardiac diseases for over a century. Quinine and digitalis are given not only where arrhythmia is present, but also where large doses of digitalis seem urgently needed and where concomitant disturbances make quinine desirable. Quinidine, a dextro-rotatory isomer of quinine, has lately been the subject of much study owing to the beneficial effects it produces in auricular fibrillation and arrhythmia. By fibrillation is meant an inco-ordinated, tremulous flickering movement of the muscle wall of the auricle. A circus movement having its path about the mouths of the great veins, has been shown to be the basis of the disordered mechanism of fibrillation and flutter of the auricles. The fibrillation of the auricle may amount to 500 a minute while the ventricular rate may be 120 to 140 and in rare case 200 per minute, because many of the impulses fail to excite any ventricular contraction. The relief afforded by quinidine is believed to be produced by the depressant effect of the alkaloid on the heart muscle which prolongs the refractory period of the auricular muscle, in this way ending the circus movements. This reduces the excitability of ventricles and auricles to a point below that at which fibrillation is possible. Most of the cinchona alkaloids lower the contractibility of the cardiac muscle. Intravenous injections of therapeutic doses in animals, 10 to 15 mgm. per kilo. corresponding to 5-10 grains in man, produce the following effects:—(1) It prolongs the refractory period of the cardiac muscle and slows conduction. (2) It depresses the excitability of the cardiac muscle, i.e.,

raises the threshold of stimulation and greater resistance to extra-systoles. (3) It lowers the rate of sinus impulse discharge. (4) It mildly depresses the vagus. (5) It produces a slight decrease of auriculoventricular conduction. (6) It increases amplitude of excursions by 16 to 100 per cent., due to greater diastolic filling resulting from longer diastolic pause. (7) Temporary fall of the systemic blood pressure and rise in the pulmonary blood pressure occurs. (8) Inconstant effect on the T-waves and inconstant alteration in response to vagus stimulation are produced.

The chief criterion for its use is a healthy myocardium. The following points may help in the selection of suitable cases:--

(1) Fibrillation of recent onset. (2) Slight dilatation of heart. (3) Absence of valvular disease. (4) Fibrillation associated with acute infection, *e.g.*, influenza. (5) Hypertrophied heart. Unsuitable cases are those with:—(1) Enlargement and valvular disease, and hearts which after rest and digitalis do not elicit evidence of reserve strength. (2) History of embolism. (3) Idiosyncrasy to cinchona derivatives. (4) Cardiac pain.

In human beings it is usually given by the mouth in the form of sulphate either in tablets or in capsules. A dose of 0.2 gm. is given on the first day and if it is well borne, it is increased next day to 0.4 gm., three or four times a day, but not exceeding the total of 2 gm. per day. If no benefit follows within 3 days, quinidine is generally not likely to do good. In the case of success the drug is omitted and readministered on recurrence of symptoms. The maintenance dose is 0.25 gm. per day. Intravenous injections are dangerous as the margin of safety is small. In about 50 per cent. of the cases the medication has no effect, and these are generally the advanced cases of heart disease with extensive changes in the myocardium. As the drug has a paralysing effect on the heart muscle, it should be given with caution and after a course of digitalis in cases of failure of compensation. Onset of frequent miniature beats or a persistently high ventricular rate are indications for cessation of treatment. In carefully selected cases the use of quinidine in cardiac irregularities is justifiable, important contra-indications being a high grade of myocardial damage. Lewis has suggested that in changing the rhythm there may be ventricular standstill for sufficiently long periods to cause death. Previous digitalisation increases the chance of success and diminishes the danger of accidents. Toxic doses impair the heart, producing sino-auricular or auriculo-ventricular block, ventricular fibrillation or gradual inhibition of the whole heart. In this case the auricles usually stop before the ventricles. In susceptible individuals quinidine may produce phenomena of hyper-susceptibility, giving rise to nausea and flushing. Rarely, quinidine may change the intra-auricular block and

fatal ventricular fibrillation may occur. As quinine and quinidine are rapidly excreted the drugs do not give rise to any cumulative effects.

Respiration. Given intravenously, these alkaloids have a depressing effect on the respiratory centres. Hydrobromides have a much weaker effect in this respect than the hydrochlorides and therefore these are preferred for intravenous administration. It has been shown that after lethal doses in cats (25 mgm. per kilo. body weight) the heart continues to beat for two minutes after stoppage of respiration.

Central nervous system. On the cerebrum, quinine has a depressing effect, though not to such a marked degree as some of the other antipyretic drugs. Because of its sedative action on the central nervous system it has been used to induce sleep, a few grains being given at bed time. Large doses may produce mental excitement such as that manifested in cinchonism. When taken for prolonged periods it may give rise to psychical derangements, which take the form of defective associative processes, flight of fancy, but these are never very marked. In rare cases loss of consciousness has been seen, accompanied by delirium, convulsions and death following symptoms of collapse. Weakening of the heart is the main cause of death, but respiration stops before the heart. Death has been recorded with a 2 gm. dose but as a rule fatal dose is 8 to 10 gm. or more. As quinine is rapidly excreted, recovery generally takes place, but deafness and defect in the sight may remain for weeks or even months. In ordinary therapeutic doses it has no effect either on the medulla or on the cord, but large doses depress these structures and the respiratory centre is especially attacked. Very large doses produce paralysis of the whole central nervous system, leading to stupor, coma and death.

Peripheral nerves. The cinchona alkaloids and their derivatives produce a slow and prolonged abolition of sensation by their direct effect on the sensory nerve endings. For this reason quinine is not infrequently employed in the treatment of neuralgia. Lately, a good deal of attention has been paid to their power of producing local anæsthesia and their potency can be judged from the fact that while 1 in 50 solution of cocaine hydrochloride will produce anæsthesia of the cornea of a rabbit, the same effects can be produced by 1 in 60 of quinine hydrochloride, 1 in 100 of hydro-quinine, 1 in 1000 of ethyl hydrocupreine (optochin) and 1 in 1200 of iso-amyl-hydrocupreine.

Strength of solutions of cinchona derivatives producing corneal anæsthesia :—

Quinine HCl	1 in 60
Cocaine HCl	1 in 50
Hydroquinine HCl	1 in 100
Ethyl-hydrocupreine (optochin)	1 in 1000
Iso-amyl-hydrocupreine	1 in 1200
Eucupinotoxin	1 in 2000

The cupreidine series have a similar though slightly less marked action. Quinidine and cupreidine compounds have also great anæsthetic properties but their action is somewhat weaker.

Quinine is often combined with urea and is used as a local anæsthetic. This combination increases its solubility and its power of penetration into the cells, but the resulting compound is decidedly weaker and has to be used in twice the strength necessary if quinine alone is used. As a rule 0.25 to 1.0 per cent. solutions are quite effective. In lumbago 5 c.cm. of a 1.0 per cent. solution injected into a muscle may relieve the pain. The disadvantages of the cinchona derivatives in comparison to cocaine and its allied compounds are that (1) injections are painful; (2) the induction of amesthesia takes longer; (3) they are more irritating and in stronger solutions may cause infiltration of the tissues and sloughing; (4) the anæsthesia produced may last for several days. These compounds also irritate the conjunctiva and their action is not deep-seated; otherwise they would be excellent anæsthetics for ophthalmic operations.

Special senses: *The eye.* Quinine and its allied compounds, when given in toxic doses, produce visual disturbances such as contraction of visual fields, diminution in acuity of vision, colour blindness leading to amblyopia and amaurosis. The development of the blindness varies enormously, some patients quickly become anauritic, whilst in others varying degrees of amblyopia supervene. The pupils are dilated and of sluggish reaction; there is central scotoma for green and red. Ophthalmoscopic examination of such cases shows constriction of the choroidal vessels; the retina looks pale and the disc hazy and oedematous. The constriction of blood vessels is probably of vaso-motor origin and it is much more marked with such derivatives as optochin; later the vessels become dilated, thirty grains of quinine taken in one dose may bring about this condition but therapeutic doses as a rule produce little effect. With large doses temporary and permanent blindness have been known to occur, probably from the effect of the drug on the nerve fibres of the ganglion cells. Generally a speedy recovery is to be expected, but in many patients the central vision is permanently damaged and in addition the light sense remains defective and the visual fields remain contracted. Colour vision may be considerably regained; a certain amount of dilatation of the pupils may remain. It is believed that most of the visual disturbances in patients taking ordinary therapeutic doses of quinine in malaria are due to parasitic emboli in the retinal vessels and not to the effect of quinine on the retinal elements. Treatment of such patients consists in giving strychnine which is a direct stimulant to the optic nerve fibres, and inhalation of amyl nitrate and oral administration of 2 grains of sodium nitrite daily, with a view to dilating the blood vessels. Digitalis and bromides have also been recommended.

The ear. The common accompaniments, ringing in the ears and deafness appear to be chiefly due to congestion of the blood vessels. Sixty grains in 24 hours may cause marked disturbances in the ear and even deafness. In rabbits congestion and ecchymosis in the internal ear were produced by giving large doses of quinine. Degenerative changes have also been noticed in the cochlear ganglia; otitis media may be set up by long-standing congestion, and permanent deafness may be produced. When giving quinine to patients with middle ear disease, the possibility of its activating a quiescent condition should be borne in mind.

Quinine has a specific action upon the special sense organs, the first sign of an overdose being ringing and roaring in the ears, accompanied by slight deafness. At the same time the eyes are affected, and there is diminution in the field of vision, photophobia and even temporary blindness. The effects are due to the action of quinine on the nervous elements in these organs.

Metabolism. This is affected in a most remarkable manner by quinine in very small doses. There is a slight transient increase in the nitrogenous constituents of the urine followed by a marked decrease, especially in urea and uric acid. Quinine is said to cause diminution of heat-production by decreasing metabolism from its action on the muscles and glands. It inhibits both the anabolic and katabolic processes of the cell, the processes of oxidation being thus markedly reduced. For this reason, economy in the metabolism of the body as a whole is secured, especially in those conditions in which katabolism has been stimulated by pathological processes. After administration of quinine in febrile conditions, urea, uric acid, sulphates, phosphates and chlorides decrease in the urine. Some drugs diminish the excretion of urea, sulphates, etc., but their deficiency in the excretion of nitrogen and sulphur in this form is counter-balanced by the larger excretion of unoxidised substances containing nitrogen and sulphur, e.g., ammonia, leucin, tyrosin, and cystin. This is not the case after quinine. The use of quinine therefore in wasting diseases such as tuberculosis, is said to be based on rationalism as it tends to check the excessive breakdown of proteins which occurs in these diseases. It is also significant that in spite of the fact that metabolism is diminished, the gaseous interchange, i.e., the absorption of oxygen and the elimination of carbon dioxide remains unaffected. This means that some nitrogenous food, which normally is used up and later appears as a solid constituent of the urine is being stored in the body and the animal, being in equilibrium, is putting on weight.

Prior's experiments on himself and dogs showed that while the urine was increased 11–12 per cent., urea was decreased 19–20 per cent., uric acid 72 per cent., sodium by 9 per cent., sulphuric acid by 34 and phosphoric acid by 23 per cent. Hardikar (1920) however showed that quinine

has no effect on the protein metabolism in health, and in malarial fever it is not possible to control tissue waste and to husband energy by means of quinine.

Effect on the body temperature. In healthy individuals quinine produces no effect on the body temperature, but in most febrile diseases ordinary therapeutic doses of quinine produce a fall of temperature. It would seem natural to connect this antipyretic action with the depressing influence of the drug on metabolism which would thus produce diminished production of heat. But against this view is the fact that oxygen intake and carbon dioxide output are not materially altered. It has been shown, however, that oxidation is not the only source of heat production and that heat may be produced by the splitting and hydration of nitrogenous molecules, in the course of which nitrogen is converted into urea. In febrile animals the body temperature falls after quinine, even when all the increased loss of heat is prevented. Calorimetric experiments show that loss of heat from the body surface is diminished after quinine. The only possible explanation could be that the antipyretic effect is due to diminished production of heat. The action of quinine in this respect is the reverse of other antipyretics, such as those derived from the coal tar. The reduction of temperature after quinine has therefore been likened to letting the fire burn low or go out in a room that is too hot, while to give antipyretics of the coal tar groups is to open the windows. The fall of temperature runs a course parallel to the nitrogenous metabolism, as measured by the excretion of nitrogen in the urine. Quinine would therefore be a very useful drug in this respect. In the presence of fever it is also said to produce hyper-glycæmia and to lower excessive concentration of the blood.

According to some observers, after small doses of quinine there is a slight rise of temperature before the usual fall; there is a corresponding increase in nitrogen excreted in the urine. This may be compared to the preliminary stimulant action of the dilute solutions on infusoria or white corpuscles, before paralysis.

Muscle. Quinine first causes a temporary increase and then a decrease in the absolute strength and the working capacity of muscle and finally death followed by immediate rigor. Dilute solutions hasten fatigue. The results are the same whether a muscle is curarised or not; the action is therefore on the muscle fibres, irrespective of their nerves. On smooth muscle the effect is similar. The total effect on muscle tissue with therapeutic doses is small. Quinine is however said to be a tonic, a word which is often abused. This term should be limited to drugs which increase the tone of muscles, *e.g.*, strychnine, but quinine is not one of these. The term is commonly employed to denote remedies which improve the general health and vigour of the patient.

Uterus. Quinine has often been employed to increase the force of contractions in the second stage of labour, under the belief that it favours the contractions of uterine muscle; it is also believed that given in large doses it has an ecbotic action. The action appears to be directly on the muscle fibres without the intervention of the nervous system, as atropine does not modify its action. According to some observers quinine inhibits the non-gravid uterus and stimulates the gravid uterus, because the distension of the fibres has rendered them sensitive to any kind of stimuli. It should be remembered that high temperature, which often accompanies malaria may in itself produce death of the *fœtus* and evacuation of the uterus. Temperature in pregnant women suffering from malaria should not therefore be allowed to go above 103°F. Experiments on isolated pregnant uteri of rats and guinea pigs show that in dilutions of 1 in 300,000 quinine produces no effect whatever, 1 in 150,000 only produces contraction under certain circumstances and 1 in 44,000, a concentration which can never be attained in the blood unless the patient is literally poisoned with quinine, produces a tonic spasm of both the circular and longitudinal fibres, which if maintained kills the *fœtus*. Dilution of 1 in 10,000 to 1 in 5,000 may produce relaxation and paralysis. Concentrations of 1 in 150,000, such as occur in blood normally after ingestion of quinine in moderately large doses, stimulate the intermittent contractions. If now some exciting cause is present such as weak membranes or a patulous os, the membranes may rupture and labour may be started. There is disagreement regarding the effect of quinine on the tone of the uterine muscle. According to some authorities a considerable increase of tone is produced but the action is not sufficiently strong to produce a tonic contraction dangerous to the *fœtus*.

Spleen and intestine. In animals under anaesthesia injections of quinine produce a marked reduction in the volume of the spleen. In pathological enlargements of this organ such as those occurring in malarial fever, administration of quinine causes contraction and reduction in its size. These effects are probably brought about by the contraction of the involuntary muscle tissue in this organ. The intestine may also be contracted.

Fate in the body. Quinine is easily absorbed from the mucous membrane, subcutaneous and muscular tissues and it circulates in the blood as quinine base. The length of its stay in the blood is very short. When quinine is given in large and continuous doses by mouth, a concentration in the blood of from 3 to 10 mgm. per litre can be obtained. Doses of 2 gm. a day must be given to obtain a concentration of 10 mgm. per litre in the blood; and when the concentration rises above this, severe symptoms of cinchonism arise. An intravenous injection of 0.8 gm. of quinine gives a concentration of 200 mgm. per litre, but the drug is rapidly removed from the blood. Of the quinine present in the blood, some is in the blood corpuscles and some in the

serum. A large proportion (about 60 per cent.) is deposited in such organs as the liver, gall bladder, kidney, supra-renals, lungs and spleen. In the liver, the quinine molecule is split up and the drug is partly destroyed. The quinine which escapes destruction in the liver and other organs, passes through the circulatory system and is eliminated as quinine base in the urine. Up till now no other recognisable derivatives have been detected. There has been difference of opinion as regards the distribution of quinine among the constituents of the blood. After absorption, the salts of quinine are carried in the blood in small amount and rapidly deposited in various tissues, the supra-renals and the kidneys receiving the most; the lymph glands and muscle tissue do not contain any and the red blood cells very little. The following distribution of quinine in different organs has been given by Ramsden :- Serum 0.1326 mgm., corpuscles 0.005 mgm., liver 14.85 mgm., kidneys 4.025 mgm., supra-renal 7.02 mgm.

Quinine occurs in the lungs in fairly large quantities. Experiments show that after ingestion per os or by injection, guinea-pigs show a much greater proportion of quinine in the lungs than in the liver. This is also the case with optochin and for that reason these compounds were recommended in pneumonia. Studies by Hatcher and Weiss (1927) show that in cats and dogs, 95 per cent. of quinine disappears from the blood in about 5 minutes, after intravenous injection but traces may be found as long as 15 hours afterwards. The alkaloid is fixed by the capillaries immediately after the injection, and they probably play an important part in returning it to the circulation. It is promptly fixed by the lungs, liver, heart, kidneys and brain in higher concentration than the average for the remaining portion of the body; it is given up rapidly so that after 3 hours scarcely any trace of quinine can be found in these organs. It is suggested that fixation by the capillaries leads to more intimate contact between the protozoa affected and the alkaloid.

Morgenroth's observation showed that quinine is preferentially taken up by the red blood corpuscles, and in that position either kills the intra-corpuscular parasites or exercises a repellant action on the merozoites which are prevented from penetrating them and therefore perish. Other workers have also confirmed the storage of quinine in the red corpuscles. It will be seen therefore that there is no agreement among observers, regarding the ratio of quinine between plasma and red corpuscles while the drug is circulating in the blood. This is due to the fact that the technique of deciding this problem is extremely difficult and liable to error. King and Acton (1921) showed that the plasma and the corpuscles contain an equal amount. *In vitro*, experiments by Akashi (1923) show that the amount of quinine stored varies with the concentration of the alkaloid, number of red corpuscles and temperature. In the presence of much carbon dioxide the cells do not store quinine; the

liver cells also behave like red corpuscles. A certain proportion of quinine ingested is metabolised; the liver has been known to destroy morphine, nicotine and other alkaloids and probably it deals with quinine in the same way. It is moreover not known whether the quinine, which is stored up and metabolised in the organs, takes any part in the destruction of the parasites. Most observers consider that it does not; according to them the only useful portion of the dose is the portion which escapes destruction in the organs and circulates in the blood. The object of quinine treatment is to attain as quickly as possible a high concentration in the blood. Clinical observations have shown that to give a dose of quinine intravenously at the correct time is the quickest and surest way of curing an attack of malaria and of causing the parasites to disappear from the peripheral blood. The action of intravenous injections is however fleeting and these should be repeated at suitable intervals.

Excretion. Of the amount taken up by the body, the greater part ($\frac{2}{3}$ to $\frac{3}{4}$) is destroyed, probably by a thermolabile ferment found in the liver; most of the remainder is excreted unchanged in the urine. Small amounts pass out with the bile and traces may be found in the sweat and saliva. Quinine is thus excreted almost entirely by the kidneys. When given by the mouth small quantities occur in the faeces, but this is due to deficient absorption. By the kidneys it is excreted unchanged and if this organ is healthy the process is very rapid, quinine appearing in urine within 20 to 60 minutes of administration by the mouth on an empty stomach. The excretion reaches its maximum in three to five hours, and this maximum rate is maintained for 3 to 4 hours, after which it diminishes. The excretion is complete in sixteen to forty-eight hours. During continued administration of large amounts, elimination keeps pace with the administration, if the daily dose is not more than 30 grains (2.0 gm.). About 40 per cent. of quinine taken is excreted in the urine, and of this quantity two-thirds is excreted in the first 12 hours, and most of the remaining third within the next 24 hours; after 36 hours only traces are detected. Sixty per cent. of the drug which is not excreted in the urine is broken up and destroyed in the body.

There is difference of opinion regarding the influence of the form of administration, division of dose, etc. on the rate of excretion of the drug. According to some the action of quinine is more rapid with soluble salts, but Giemsa has shown that this is only true after injection. Soluble salts like quinine bihydrochloride and insoluble salts like quinine sulphate are excreted at the same rate in the urine. The amount of quinine excreted and rate of excretion of the alkaloid are the same whether the drug is given by the mouth, intramuscularly or intravenously. The consensus of opinion is that large spaced doses are most efficacious; that the greatest concentration in the blood is reached in about six hours and the maximum therapeutic effect somewhat later. It has

been variously stated that excretion or destruction is increased during fevers. In severe nephritis and in cardiac decompensation none may be excreted. It is now agreed that much of the drug is destroyed and that the remainder is excreted unchanged by the kidneys. The idea that part was converted into chinicine (quinotoxin), which is formed when quinine is heated with organic acids, is abandoned. Quinine is considered by some authorities to have a well-marked diuretic effect by its dilating effect on the kidney vessels. It is said therefore to be useful in certain forms of œdema and dropsy, especially those due to anæmia and cachexia.

The quinine concentration in the blood remains constant 4 to 8 hours after intramuscular and 2 to 12 hours after intravenous injection, as the excretion during this period shows no fall. The excretion rate falls after the first day. In malaria, the excretion rate is similar to that in health but variations are greater after oral administration.

CHAPTER XIX

THERAPEUTICS OF CINCHONA ALKALOIDS

The use of cinchona in the treatment of malaria dates as far back as 1657. The ship surgeons who visited India from 1657 to 1804 used cinchona bark in the treatment of ague. From 1804 to 1847 the cinchona bark treatment of fevers was entirely abandoned in India and treatment by purgatives such as calomel, and venesection was resorted to. In the meantime Pelletier (1820) discovered quinine which then was a mixture of all the alkaloids of cinchona bark. Subsequent to this the use of the bark declined and quinine sulphate gradually took its place. In the meantime other alkaloids such as cinchonine, cinchonidine and quinidine were discovered, and in 1866 the Madras Cinchona Commission was appointed to test their relative merits in the treatment of malaria. The tests were rough and mostly clinical and the Commission came to the conclusion that quinine was preferable to the other alkaloids. Next MacGilchrist (1914) tested a number of these alkaloids clinically, and he placed them in the following order from point of view of their anti-malarial efficiency:—(1) Hydroquinine hydrochloride, (2) Cinchonine sulphate, (3) Quinine sulphate, (4) Quinidine sulphate, (5) Optochin hydrochloride, (6) Cinchonidine sulphate, (7) Quinidine. Acton (1920) found dextro-rotatory alkaloids (except cinchonine) more toxic to *P. caudatum* than their laevorotatory isomerides. The corresponding hydro-alkaloids were less toxic. Further, the degree of alkalinity of the environment is of very great importance. The decision as to which alkaloid should be employed rested between hydroquinine, quinine and quinidine. Later experience showed that quinidine has a depressant action on the heart and in some patients untoward effects were produced by it. Cinchonine is a toxic alkaloid and produces irritation of the gastro-intestinal tract and symptoms of cinchonism. Cinchonidine was the least toxic of all and in ten

grain doses was quite effective against malaria. A combination of these alkaloids such as that occurring in 'cinchona febrifuge' or tota-quina was just as effective in the treatment of malaria as quinine. Sinton (1924) showed that in malaria there was some evidence of acidosis and therefore he advocated large doses of alkalies along with quinine.

QUININE IN MALARIA

As a curative agent. Quinine still holds the foremost position in the treatment of malaria, though the antimalarial value of the other alkaloids of cinchona bark is being more and more appreciated. In considering the relative therapeutic value of the different alkaloids it is of great importance to take into account their effect in causing harm or inconvenience to the patient. It may be said in favour of quinine, that it can as a rule be given in sufficient doses and for a sufficiently long period without fear. Cinchonine is more nauseating than quinine and is liable to produce nausea and blurring of vision. Quinidine is also more nauseating and has a powerful depressant action on the heart. Cinchonidine is neither very toxic nor irritating, but it is distinctly the weakest of the four chief alkaloids. Ethylhydrocupreine, although it has a powerful action, has a marked tendency to produce blindness. Quinine is therefore to be preferred.

There is still a considerable difference of opinion regarding the methods of administration, dosage and duration of treatment. This is largely due to the varying incidence, severity of infection and the resisting power of the several varieties of malaria in different parts of the world. It is therefore very difficult to lay down any hard and fast rules regarding these points, which may be of universal application.

The following main principles may be laid down in the treatment of malaria with quinine.

1. The alkaloid should be administered immediately after the diagnosis of malaria is assured, irrespective of the stage of the disease and the height of fever.

2. Quinine should always be given by the mouth when it can be administered and absorbed by that route.

3. The administration of the alkaloid must be continuous over a period of at least 5 to 10 days. Some authorities recommend considerably longer courses but these appear to be unnecessary.

4. Quinine will not act efficiently if the liver is sluggish or congested, or if the gastro-intestinal tract is disordered. To obviate these difficulties a brisk purgative, *e.g.*, 2 to 5 grains of calomel or an ounce of castor oil should be given on the day on which the quinine treatment is begun. Quinine should preferably be given in the form of solution and should be well diluted rather than in a concentrated form. This will aid absorption and will prevent its upsetting the digestive functions. If tablets or pills have to be given they should be crushed and given with plenty of fluid. The patient should remain in bed during treatment.

5. The administration of quinine should be so timed that it reaches the blood stream at the moment when the latter is at its alkaline tide. According to Acton and Chopra (1928) the portal blood stream reaches its maximum alkaline tide some $2\frac{1}{2}$ hours after a meal.

6. The alkaloid should preferably be administered with alkalis as these tend to increase the absorbing power of the intestinal mucosa for cinchona alkaloids from the small intestine.

The treatment of the disease can be divided into:—

(a) Treatment of the attack.

(b) After-treatment.

(a) **Treatment of the attack.** The patient should be put to bed before the quinine treatment is started and he should be kept in bed for at least three days if not longer, however mild the attack may be. Twenty to 30 grains quinine should be given daily, divided into 2 or 3 doses, according to the weight and age of the individual. Some clinicians give the drug every six hours on the assumption that the action of a dose lasts for six hours. As the febrile paroxysm which follows sporulation of the parasites usually begins between 2 a.m. and 12 noon, it is held that doses should be given commencing at 12 midnight. Whatever method is adopted the parasites disappear from the

blood and the fever ceases within 24 to 72 hours, but the treatment should be continued for at least five days after the fever subsides. Sometimes, quinine cannot be given by the mouth owing to persistent vomiting, especially in pernicious cases. In such cases the best method of administration is by the intramuscular route. Fifteen grains given in this way produce cessation of vomiting and other acute symptoms within a few hours, and disappearance of parasites in 18 hours. Quinine can then be given by the mouth.

(b) **After treatment.** In the treatment of all cases of fever it should be remembered that it is wrong to continue giving large doses of quinine for many days if it is not producing any effect. Quinine does good quickly if it is going to be of any use at all. Whether treating ordinary cases of primary attack or of relapse, it is seldom necessary or advantageous to give 20 to 30 grains of quinine daily for more than 7 to 10 days. If the fever does not subside some other factor is responsible for its production and the treatment should be changed.

No clear indication however has yet been obtained regarding the method of treatment of malaria with quinine, which would bring about disinfection with a minimum quantity of the drug in a reasonably short time, so that a relapse does not occur. This is due to the fact that the virulence of different strains of parasites in different parts of the world and their reactivity to various drugs varies very widely. It is not reasonable therefore to expect that all cases will respond in the same way to a standard plan of quinine treatment. That is the reason why many different schemes of treatment have been evolved to suit different conditions. A large percentage undoubtedly get cured after quinine treatment for seven to ten days in India, a smaller percentage may require longer treatment. The percentage of uncured cases is said to be small. Cure is usually signified to mean freedom from relapse and from parasites in the blood, after the treatment has ceased for two months. In an endemic malarial locality this is difficult to establish, as reinfections are taking place. Benign tertian malaria is especially resistant to quinine treatment, and it is believed by some that nothing short of a three months' course in the non-malarial season and a four months' course in the malarial season (when reinfections are occurring) will be effective in destroying all the parasites. Such a scheme of treatment is however impracticable, harmful and is not recommended. It is preferable to give a 7 to 10 days' course after each attack.

The following plans have been suggested for prolonged treatment:—(a) 10 grains of quinine once daily, (b) 30 grains of quinine on each of two consecutive days, *e.g.*, Saturday and Sunday, each week, the amount being preferably taken in 4 separate doses, (c) 30 grains of quinine only once a week, *e.g.*, Sunday, in four doses per day, (d) 15 grains on each of two consecutive days, *e.g.*, Saturday and Sunday each week, (e) 15 grains of quinine only one day each week, *e.g.*, Sunday. The amount in the last two plans is taken in one dose and is suitable for mild attacks. The daily dose plan would appear to be the best as it is difficult to state on which day the parasites will appear in the circulation in sufficient numbers to produce a paroxysm. Ten grains given every day will probably be sufficient to destroy the parasites in the circulation. Larger doses given at longer interval may compensate, but the chances of paroxysms recurring are greater. Such doses may not prevent reinfection of the patient, and whenever it is possible these should be prevented by other means. James (1922) laid stress on the time of taking quinine and considers that success of treatment depends on this. The dose, he considers, must be taken 2 to 3 hours before the onset of the febrile paroxysms. If a relapse occurs the whole course including the 5 days treatment of the attack should be repeated. The removal of patients from an endemic area to a better locality is often helpful. Patients suffering from malaria who do not do well in tropical climates immediately start improving when removed to a better climate. It should be remembered that removal to a very cold climate may light up an infection and bring about a severe relapse.

A number of standard treatments of malaria with quinine have been suggested to suit various localities.

(1) Ronald Ross (1921) advises during the first two weeks, 15 grains of the hydrochloride or sulphate of quinine daily; then 10 grains daily for six days in the week for eight weeks making a total of 690 grains. Benign tertian infections yield rapidly to this treatment as regards the febrile attacks, but are more difficult to cure in the sense of preventing further relapses than the malignant tertian type. Twenty-four thousand cases treated by the Ministry of Pensions were cured by this plan.

(2) The United States Malaria Commission (1921) recommends 30 grains (2.0 gm.) quinine sulphate daily in 3 doses while the symptoms last and for 4 days after; this is followed by 10 grains every night before retiring for 8 weeks. This course is said to have cured 90 per cent. of cases in the southern United States where malaria is not so severe. In Palestine this course was insufficient to cure chronic cases. The Jamaica Tropical Diseases Conference did not consider it advisable to recommend this method for universal application.

(3) Hehir (1927) suggests a three months' course:—

First week—(a) In benign tertian, 30 grains on the day of the next expected attack, and on alternate days until 120 grains have been taken during the week.

(b) In quartan, 30 grains as before, and on every third day until 90 grains have been taken.

(c) In malignant tertian, as for benign tertian.

(d) In double benign and double malignant tertian, 30 grains daily for three days, and then 20 grains daily for another three days, none on the seventh day.

Thereafter the course is the same for all types.

Second week.—15 grains daily.

Third & fourth weeks.—10 grains daily, with 20 grains every 7th day.

Fifth to eighth week.—10 grains daily.

Ninth and tenth weeks.—5 grains daily, with 10 grains on two consecutive days each week.

Eleventh and twelfth weeks.—5 grs. daily, with 10 grs. once a week.

(4) In South Africa, Pratt-Johnson and Gilchrist (1921) advise 10 grains of quinine 3 times a day for three weeks, then 10 grains twice a day for one month followed by 10 grains once a day for two months. They found the relapse interval was 14 days in benign tertian and 12 days in malignant tertian cases; the crescents disappeared, on an average, in 15 days with 25 grains of quinine a day.

(5) Panama Canal Zone Standard course (1925) is more drastic. The patient is given a dose of 2 to 3 grains of calomel followed by a dose of Epsom salts before the treatment is started. Fifteen grains of quinine are given three times a day until the temperature settles down and is normal for 5 to 6 days. Then ten grains are given three times a day for 10 to 14 days. This course cured the vast majority of malignant tertian infections.

It is not advisable to give such large doses as 30 to 40 grains a day for more than a week or ten days whether treating primary infection or a relapse, as it upsets digestion, and prolongs convalescence. It is also said that doses of 15 to 20 grains twice a week greatly reduce the number and severity of infections by limiting parasitic development, and help to prevent severe symptoms and establish tolerance. Thirty grains daily for 8 weeks among the British troops in the Punjab gave a relapse rate of 6.5 per cent. but it interfered with digestion, metabolism, etc.

(6) Mayne and Carter (1919) give 800 grains as follows:—

40 grains of quinine sulphate for 5 days	...	200 grains.
20 " " " " 10 "		200 "
10 " " " " 20 "		200 "
5 " " " " 40 "		200 "
		<hr/>
		800 "

(7) Ochner advises 2 grain doses of quinine every two hours, day and night for 48 hours repeated after six days' interval. It is very troublesome, less efficient and relapses are more frequent.

These treatments when properly carried out will eradicate infection in ordinary cases when re-infections are prevented. In induced malaria complete disinfection has been produced with a dose not exceeding 40 grains.

Synergist of Quinine. Acton (1921) first recommended the association of alkalies with quinine, with the idea of reinforcing its action. He found that the toxicity of this alkaloid on paramoecium and bacteria was increased when the hydrogen-ion concentration of the medium was on the alkaline side. Sinton and Lal (1924) gave large doses of alkali to patients to produce such a condition in the body. They found by means of Sallard's clinical test of giving by the mouth, 4 gm. of sodium bicarbonate well diluted, then 2 gm. an hour later, followed by 2 gm. every half an hour and testing the urine with litmus till it becomes alkaline, that there was acidosis in malaria. Acton and Chopra (1925) showed that the administration of alkalies before quinine, increases its rate of diffusion through the mucous membrane of the intestines. By a previous administration of alkali the concentration of quinine in the mesenteric vessels can be greatly increased.

Alkaline mixture A.

Sodium bicarbonate	60 grains.
Sodium citrate	40 ,,
Water	1 ounce.

Quinine mixture Q.

Quinine sulphate	10 grains.
Citric acid	30 ,,
(Or Dilute Sulphuric Acid)	30 min.
Water	1 ounce.

All cases are given calomel and magnesium sulphate before the treatment; for the first day of treatment 3 doses of A are given at 7-30, 9-30 and 11-30 a.m.; half an hour after the last dose one dose of Q is given. At 6 p.m. a further dose

of A is given followed 15 to 20 minutes after by one of Q. For the next 4 days one dose of A is given three times a day at 7-30, 11-30 and 6-0 p.m., followed on each occasion by a dose of Q. For the remaining 2 days one ounce of A is given morning and evening followed 15 to 30 minutes after by a dose of Q. Controls were given mixture Q only but no alkali. The total quantity of quinine given in 7 days was 180 grains and the criterion of cure was non-appearance of parasitic relapse during 8 weekly examinations. Sinton (1930) expressed the opinion that a one-week course suffices in the majority of cases. Though a prolonged course of treatment gives a slightly higher rate of permanent cures, the difference is not sufficient to warrant the extra time or expense. He also recommends plasmoquin 0.015 gm. daily throughout the course, to be given after food. If a relapse occurs the whole course should be repeated for one week, and continued for a second week, with two doses instead of three. No plasmoquin should be given in malignant tertian cases, but in benign tertian the dose of plasmoquin should be increased to 0.02 gm. daily during the 14 days' course. In chronic relapsing infections, the three daily doses of A and Q mixtures are given during the first week, followed by two daily doses for two weeks, a total of 0.03 to 0.04 gm. of plasmoquin is given in two daily doses after meals. If this treatment is carried out properly not more than 1.0 per cent. should remain infected.

If the alkaline mixture produces gastric disturbances, 2 drachms of sodium citrate in 2 ounces of water is taken slowly. Eighty per cent. of 800 malignant tertian infections were cured in a week by 30 grains of quinine daily with alkalies, and it is said that crescents disappeared three weeks after the asexual cycle. Alkali treatment can be combined with cinchona febrifuge. In severe cases a dose of alkaline mixture followed by 1 ounce of quinine mixture 15 to 30 minutes later, may be given at once without waiting for the purgative, but in these cases alkaline treatment should be continued till the urine becomes alkaline. In severe cases of malignant tertian malaria, the amount of sodium bicarbonate may be increased to 90 grains dissolved in two ounces of water. With this treatment in

Sinton's series, 28 per cent. of benign tertian relapsed as compared with 40 per cent. without alkali treatment; whilst in case of malignant tertian the relapse rate was 15 per cent. as compared with 79 per cent.

Quinine and alkali-producing substances (citric acid is converted into an alkali in the gut) can be prescribed in one mixture especially for outpatients in which it is not possible to carry out Sinton's treatment.

Quinine sulphate	10 grains.
Citric acid	30 "
Magnesium sulphate	30 "
Chloroform water	1 ounce.

This mixture is given 3 times a day 2½ hours after food for one week. The dose is then reduced to 1 ounce a day for further two weeks. Citric acid is converted in the gut into carbonate and this acts as an alkali.

After-treatment is an important consideration in malarial patients treated with cinchona alkaloids. At the end of a course the patient is anæmic and run-down and a combination of iron, arsenic and strychnine in small doses is often beneficial in building up the resistance of the patient and in the destruction of the remaining parasites not destroyed by quinine treatment. In some cases it has been found that quinine apparently produces little effect and the patients relapse. In such cases a dose of Novarsenobenzol, before quinine treatment, is helpful to overcome infection but this should be given with caution.

Provocative agents. Believing that the appearance of parasites in the blood in chronic cases of malaria renders them more liable to the action of quinine, certain substances have been used as activating agents to produce malarial relapses for securing the reappearance of asexual parasites in the peripheral blood. For this benzol in 0.1 to 0.5 mgm. doses has been given by the mouth in gelatine capsules or by injection. Subcutaneous or intramuscular injections of normal horse serum, milk, and strychnine nitrate 2 to 3 mgm. are used; application of X-Ray, ultra violet rays, cold douches, ice, etc., to the abdomen have been suggested. These methods are not very reliable and the

effects produced may not be immediate; several days may elapse before the parasites appear in the peripheral blood. Adrenalin, 1.0 mgm. (1 c.cm. of 1 in 1,000) subcutaneously, gives the highest percentage of positive results by producing a marked but temporary contraction of the spleen volume. Liquid extract of ergot 30 minims, 5 doses in all, orally, also thyroid extract and injection of pituitrin and salvarsan have been recommended; the last however is not without danger. Berberine sulphate in doses of 0.2 gm. sometimes acts well, 8 to 10 doses being given daily. Malaria may persist in latent form for years, the parasites lurking in the bone marrow and spleen.

Dosage. In non-malarious countries very small doses such as 2 or 3 grains are given. In tropical countries, the tendency is rather towards giving too large doses. It has been said that less than 20 grains of quinine in a day in an adult has no curative effect in malaria. This is not borne out by James' observations with induced malaria, who found that a few grains a day kept the patients suffering from induced benign tertian infections free from paroxysms for months. With such small doses however relapses occurred after long periods. Generally 20 to 30 grains by the mouth in 24 hours according to the weight of the individual, should be regarded as the maximum dose. Such doses always control malarial fever and when they do not, either the method of administration is at fault or the diagnosis is wrong.

A maximum dose of ten grains of the sulphate or hydrochloride by the mouth, three times a day for an adult, given for one week is quite sufficient to cure 70 per cent. of fresh malarial infections. In relapsing cases 5 to $7\frac{1}{2}$ grains twice daily for one month in the case of malignant tertian infections and three months in the case of benign tertian and quartan infections are recommended by some. Doses larger than 20 to 30 grains daily lead to toxic symptoms, especially in weak individuals and are an absolute waste of the drug. The consensus of opinion at present is that a 7 to 10 days' course of treatment with 20 to 30 grains of quinine according to the weight of the patient is sufficient in all forms of malarial fevers. If there is a relapse, the whole course should be repeated.

The liver of rabbits is damaged by giving repeated intravenous injections of quinine, the cells of the parenchyma showing degeneration and fatty infiltration; the same may happen in man with large doses of quinine. Amounts larger than 30 grains a day are, therefore, by no means devoid of danger. Nierenstein (1920) stated that over 30 grains of quinine per diem is liable to injure the kidneys and cause albuminuria. It should not be forgotten however that acute and sub-acute parenchymatous nephritis occurs as an accompaniment of malaria and is readily benefited by quinine treatment. Massive doses also depress the cardio-vascular system and retard development of natural immunity on which the cure of the disease depends (McCarrison and Cornwall).

Quinine should not therefore be given in doses larger than 30 grains daily unless there is any special reason; even such small doses as 5 grains twice or three times a day given under rigid supervision are sufficient to cure an attack in persons weighing 100 pounds, but such small doses are not recommended for routine administration. It is preferable to give the larger doses already suggested, *i.e.*, 10 grains twice or three times a day.

Causes of failure of quinine therapy. If quinine is properly administered and absorbed it is bound to cure a large majority of the patients. The causes of failure may be:—(1) Adulteration of quinine. Quinine adulterated with lime, starch and other inert substances to the extent of 60 or 70 per cent. has not infrequently been met with in India; this is also the case with tablets. (2) Faulty preparation. Tablets may be prepared with unsuitable media and may have a coating quite impervious to water. (3) Non-absorption from the gastro-intestinal tract due to gastro-intestinal disturbances produced by the drug itself or complicating diseases such as ankylostomiasis, enteric, etc. (4) Low individual resistance. It is well known that some persons catch infection quickly and get rid of it with difficulty. (5) Use of insufficient doses. Hospital mixtures supposed to contain 10 grains to an ounce have been found to contain 1 to 2 grains in India. (6) Some of the patients may not be taking the quinine prescribed for them

owing to their dislike or prejudice against the drug, and they may be deceiving the physician. This can be immediately tested by taking 5 c.cm. of urine, boiling, and filtering the albumin if present and adding a few drops of Tanret Mayer reagent. A precipitate is formed if the alkaloid is being excreted in the urine. The drug should be given in hospitals by a responsible individual who sees that the mixture is swallowed. One or more of these factors may account for the failure of quinine to cure malaria. Intramuscular treatment may succeed in certain conditions when quinine by the mouth has failed for obvious reasons.

When quinine is being administered the physician should make sure:—

1. That quinine prescriptions are in full strength. There is evidence that mixtures in India are sometimes much below strength.

2. That the patient swallows and retains every dose prescribed and that he does not omit to take a single dose of the standard course given. Many causes may lead to omission, *e.g.*, vomiting may occur or the patient may wilfully reject a dose.

3. That the patient is absorbing quinine or any other alkaloids given. This may be ascertained by testing the urine.

Relapses. Relapses occur frequently in malaria. Administration of iodides, adrenalin, sera or vaccines, exposure to ultra-violet rays, excessive heat or cold, bring about a relapse and should be avoided. In spite of proper treatment with quinine many cases relapse. In addition to the selective action of quinine on the type of parasite involved, the chronicity or acuteness of the infection is an important factor. Sinton and Bird (1929) found that quinine cured 76 per cent. of primary infections, but in chronic cases it cured only 32 per cent., the balance all relapsed. Chronic benign tertian infections are more difficult to eradicate. These results were corroborated by treatment of induced benign tertian malaria for the cure of mental diseases, which was easily amenable to quinine; the relapse rate was only 1 to 3 per cent. with 30 grain daily doses for three days. The reason why primary infections of

benign tertian are more readily cured than chronic infections is not understood; some observers have stated that the parasites become more resistant.

So-called Quinine Fever. By this term is meant pyrexial phenomena without any or only a few malarial parasites occurring in patients taking small or medium doses of quinine. This is not produced by the alkaloid, as was supposed but is probably due to administration of insufficient quantities of quinine which are unable to control the infection. If the quantity of the drug is increased and adequate doses are given for 3 or 4 days at proper times, the fever disappears. Chopra and Das Gupta (1933) however observed a distinct increase in the parasites in the blood after intravenous injections of quinine in man and monkeys.

MODES OF ADMINISTRATION

Quinine may be given by the mouth, subcutaneously, intramuscularly, intravenously or per rectum. By all these methods it is absorbed into the circulation.

Oral administration. On account of the convenience of administration, the oral method is the one of choice. It may be given as a powder, in solution, in cachets or in the form of pills or tablets. When given in solution it is more readily absorbed than in any other form and therefore, this is usually employed. Tablets are more convenient and are less unpleasant than the solution, but they may not be absorbed. Even quinine in powder form is not recommended by many authorities. The usual mixture employed in hospitals is 5 to 10 grains of quinine sulphate, with 5 to 10 minims of dilute sulphuric acid in an ounce of water. Some prefer the bisulphate or hydrochloride, but these are more expensive. There is no evidence to show that the soluble salts are any more effective than the insoluble sulphates, though the absorption of the latter is somewhat slower. The powder and tablets take a longer time to absorb than the solution, but whether given in solution or in solid form, the alkaloid is absorbed into the circulation quite readily. The form of administration adopted should be such as to suit the individual patient. Uncoated tablets whether of the sulphate or of the

soluble salts, if fresh, are readily dissolved and are absorbed. If there is any doubt, they should be crushed and then administered. Some physicians prefer to give quinine in solution during the stage of active fever and to carry on with tablets during convalescence. The clinical condition of the patient is the best guide in deciding what method should be adopted. The condition of the tongue is an excellent indication of the state of the gastric mucosa. In ordinary attacks the tongue is moist and slightly furred, and under these circumstances the alkaloids are absorbed very well from the gut. If the tongue is dry, red and cracked, quinine is absorbed badly, and in such cases other means should be adopted. Quinine is generally absorbed readily from the gut; even in cases of malaria complicated with dysentery, quinine has been shown to be absorbed. If nausea and vomiting are present or in the bilious vomiting of malignant tertian infection, it is useless to give quinine by the mouth, as it cannot be retained. Vomiting in malaria has been attributed by some to hypo-adrenia, and it is said to be stopped by adrenalin in doses of 0.5 to 1 c.cm. of a 1 in 1,000 solution, by the mouth or by injection. Provided it is retained, quinine by the mouth is as efficacious as by injection, especially if it is given in the form of a solution, as regards its immediate effects on the fever, on the parasites and in the prevention of relapses. Experiments have shown that in solution it is absorbed with as great rapidity and appears in the urine almost as rapidly as when given intravenously. It is, therefore, the safest and the best method except when its effects on the alimentary canal are not desirable, or some other contra-indications are present.

The rapid absorption of the alkaloid and its quick disappearance from the blood, indicate the importance of ascertaining for each case, the time at which the drug should be administered, in order that it may destroy the vulnerable stages of the parasites. In clinical work James recommends that two facts should be remembered:—(1) sporulation begins about 2 hours before symptoms manifest themselves, (2) that the effect of a dose of quinine by the mouth begins within half an hour after its ingestion and lasts for more than six hours. He stresses the advantages of giving the drug 2 or

3 hours before the attack is expected. When more than one group of parasites are present, as in malignant tertian infections, sporulation occurs at irregular intervals and the plan of giving the drug at short intervals is the best. Others hold that quinine should be started when the schizonts are very young, as growth then ceases and degeneration ensues; if it is given when the schizonts are half grown, some are killed, some degenerate, while others carry on to sporulation. Quinine given during sporulation does not stop the paroxysms.

Experience shows that best results are obtained when these alkaloids are given 2 or 3 times daily in adequate doses. As the concentration of the alkaloid rapidly falls between 4 to 8 hours after ingestion it is considered advisable to administer the doses at intervals not longer than 6 hours.

The older writers recommended that quinine should not be given during fever, and even now this idea prevails in the mind of the public. There is no basis whatever for this belief. Even high fever is not a contra-indication for its administration. In malaria, quinine should be given regularly and continuously irrespective of temperature. Quinine has been shown to be just as effective in the febrile period as in the non-febrile period. It has also been said that quinine should not be prescribed with free organic acids as quinotoxin is formed, which is very poisonous. That is not true because quinotoxin is not a toxic substance.

Quinine tablets. There has been a great deal of controversy lately regarding the use of tablets. They have been condemned as 'brick bats', and some brands have been shown not to dissolve in weak acid solution even if kept in it for weeks. Alport (1919) thinks, quinine in tablet form is valueless and says it should never be used. Sugar-coating has been blamed for non-absorption of quinine. The fault really lies in the vehicle. Leger tried tablets of hydrochloride of quinine in 145 cases, testing the urine by Tanret Meyer solution. The alkaloid appeared in the urine in 2—2½ hours, was at its maximum in 5 to 10 hours and disappeared from the urine in 27 hours. All showed the presence of quinine, which indicated absorption when administered in this form. When using

tablets care should be taken that these are not too old and have not an impervious coating on them. If this precaution is taken, absorption is bound to take place.

Rectal administration. Quinine is much too irritating and in concentrated solutions may actually produce necrosis of the mucous membrane. This method is therefore not satisfactory and is rarely employed. Dysentery-like symptoms were produced with 30 grains of quinine in 2 to 4 ounces of water. The absorption of quinine by this route is uncertain and poor, and about three times the normal dose is required. The drug is seldom retained long on account of the pain and tenesmus which is produced. If diarrhoea or irritation of the bowel is present the solution is rejected. When it has to be given by this route it is advisable to give it in the strength of 10 to 15 grains in 4 to 5 ounces of warm normal saline mixed with 10 minims of tincture opii. The fluid is slowly injected with a rubber catheter. Fletcher (1924) has shown that absorption of quinine by the rectal route, as judged by testing the urine with Meyer's reagent, is poor, irregular and unreliable. He advises that it should not be given by this route if any other method is practicable.

By subcutaneous route. This method has been used though some physicians condemn it. Subcutaneous injections are painful and liable to produce necrosis; they are said to be followed by extensive and dangerous abscess formation and even tetanus. On the other hand it is said by some to be perfectly harmless and ensures rapid absorption of the drug. The manipulation is simple and can be safely entrusted to an assistant. In Russia subcutaneous injections of 0.5 to 1.0 gm. of quinine hydrochloride are given in all cases, in combination with anti-pyrin and iodine. Rarely, subcutaneous tumours have formed after injections of quinine.

Intracutaneous injections of 0.25 to 0.5 per cent. solutions of quinine hydrochloride have been suggested in the treatment of chronic malaria. Very small doses of quinine given by this method are said to be effective by anti-body formation.

By intramuscular route. This method of administering quinine is simple, but it should be carried out with strict aseptic

tic precautions and the skin should be thoroughly sterilised with tincture of iodine. The usual indications for administration by this route are blackwater fever, bilious remittent fever, persistent vomiting, drowsiness, or mental affections.

The syringe and the needles must be kept in absolute alcohol which is washed out with ether before the injection or they should be thoroughly boiled. It is advisable to use ampoules or sterules, but if these are not available the solution prepared for injection should be carefully sterilised. Bihydrochloride of quinine, preferably dissolved in distilled water, is employed and it should be thoroughly boiled. Sergeants advise that the strength of the solution should not exceed 3 per cent., but injections of dilutions as weak as 1 in 150 are known to have caused extensive necrosis of muscle and nerve tissue. If bihydrochloride of quinine is painful, solutions of urethane quinine or quinine and urea have been recommended. It is preferable to use dilute solutions, *i.e.*, $7\frac{1}{2}$ to 10 grains of the hydrochloride or bihydrochloride dissolved in 3 or 4 c.cm. of 0.85 per cent saline rather than in 1 to 2 c.cm., which is usually done. After injection the part should be massaged and collodion applied. The situations recommended for giving the injections are:—

(1) The gluteus maximus avoiding the line of the great sciatic nerve. This is the best situation, the spot selected being about 2 inches below the middle of the crest of the ileum. The needle should be introduced perpendicularly and if the point strikes the bone it should be withdrawn about a quarter of an inch and the quinine injected into the muscle. Care should be taken not to inject any into the subcutaneous tissue, as this will cause pain, stiffness and inflammation and very frequently an abscess.

(2) The cellular and muscular tissue below and external to the apex or angle of the scapula. The advantages of this site are that the injections are painless, there is no danger of damaging important nerves, the operation is not visible to the patient and the solution is readily absorbed.

(3) The vastus externus about its middle on the outer side of the thigh.

(4) The deltoid muscle avoiding the line of the musculospiral nerve. The best place is 2 inches below the acromion process.

The injections should not be given in the same place every day as this may produce necrosis and abscess. When the neighbourhood of a previously injected site is selected, inject in the circumference of a circle keeping at least half an inch away from the previous puncture mark. It is advisable to stop the injections and administer quinine by the oral route as soon as the paroxysms have been controlled.

Considerable differences of opinion prevail with regard to the advisability and efficacy of intramuscular injections of quinine. Some authorities maintain they should never be employed, while others consider them as invaluable in severe cases, especially the dangerous subtertian and also benign tertian infections which do not respond to oral administration.

According to Fletcher (1924), quinine given intramuscularly causes serious mutilation. The drug by this route is said not to be absorbed so quickly as when given by the mouth, nor is it more potent in preventing relapses. It produces immediate necrosis of the tissues into which it is injected; the dead muscle is usually not absorbed for a few weeks and may remain as a source of disease, forming an excellent nidus for the growth of bacteria from the blood stream. Cases of severe mutilation in the form of paralysis from injection near a nerve, or contraction of muscles from severe suppuration are frequently seen. Injection in the neighbourhood of a large nerve such as the sciatic, produces excruciating pain lasting for days; paralysis of muscles and contractures may occur. It is alleged that quinine given intramuscularly has certain advantages over the oral route and briefly stated these are:

(1) Its action is said to be more rapid and more vigorous. But it has been found that with intramuscular injections quinine appears in the urine (Meyer's test) on an average in 60 minutes, while if taken by the mouth in the form of a solution it appears in about 30 minutes. The action therefore cannot be more rapid.

(2) The effect of intramuscular injection is said to be more prolonged. It is believed in some quarters that quinine given by intramuscular route acts as a kind of reservoir and in this way a steady concentration of quinine is maintained in the blood. The origin for this belief is not known. It is found by actually testing the urine with Meyer's reagent that by whichever route it is given, quinine disappears from the urine in about 46 hours. Experiments on guinea-pigs show

that a large amount of quinine is absorbed after injection and only a small fraction of the total quantity injected can be found at the site of injection.

(3) It is said to have a greater power of preventing relapses. Rennie and Acton (1921) found in a malaria depot in the Himalayas (Dagshahi) that the percentage of relapses was the same whether the quinine was injected or given by the mouth.

(4) The therapeutic value of quinine given in this way is said to be greater. A number of medical men believe in the superior efficacy of intramuscular injections, on clinical grounds. Careful experiments have shown that there is little difference between the oral and intramuscular methods; if anything, the advantage is with the oral method. The reason for this belief probably is that by the oral route, administration of quinine has to be left to patients, who may or may not take the full dose of this unpleasant drug. Intramuscular injections are given by the physician himself and it is certain that a known quantity of quinine is introduced into the system. Besides it is not infrequently found that a mixture supposed to have ten grains of quinine has one or two grains only. The urine of patients taking quinine mixture should be frequently tested with Meyer's reagent to see if the alkaloid is present in the urine. This rough method is very useful.

The fact that necrosis of tissues is a constant accompaniment of intramuscular injections is not sufficiently appreciated by practitioners. Experiments by Acton and Chopra (1923) on rabbits and guinea-pigs showed that 24 hours after injection of dihydrochloride of quinine and other alkaloids (quinidine, cinchonine and cinchonidine) in the concentrations in which they are employed clinically, they produced very extensive oedema of the subcutaneous tissues and muscles round the site of injection; hyperæmia of vessels was very marked and hæmorrhages were present in the substance of the muscles. The bases of these alkaloids were found precipitated in the tissues, and muscles and fascia round the site of injection were friable and necrosed. In one case where the injection was given near the sciatic nerve the sheath showed signs of extensive damage. The damage to the tissues was marked on the 3rd day, but by the 6th day oedema and hæmorrhage had disappeared completely, while necrosis was still visible on the 10th day. Manson Bahr showed that continuous injections at the same site gave rise to patches of necrotic tissue about the size of an almond, but that there was no indication of pus formation. In weak, anæmic and debilitated subjects such dangers may exist. Fibrous tumours have occasionally been formed by irritation produced by quinine.

Cases of tetanus have occurred after quinine injections, but these are generally due to faulty technique. Semple considers that necrosis of muscle caused by injection of quinine forms a suitable nidus for the development of tetanus spores which are taken up by leucocytes from

the alimentary canal and deposited there. Recent work of Gye and Cramer on kataphylaxis has shown that such a possibility does exist. It has been shown that tetanus spores washed free of toxins and injected into an animal do not produce tetanus. If after some months in this animal, quinine is injected, tetanus develops at the site of injection of the alkaloid. This is due to the rupture of local defence mechanism. Quinine produces necrosis of tissues and this hinders the oxidation processes in the cells, the anaerobic conditions thus set up allow the spores to develop.

It will be seen, therefore, that intramuscular injections of quinine should not be given lightly or without most rigid attention to efficient aseptic precautions, not forgetting that tetanus spores are not killed even at 100°C . for a certain length of time. It is not justifiable to give quinine by this route in the treatment of ordinary cases of malarial fever when the patient can take the drug by the mouth. It should be reserved for severe cases of malignant tertian malaria with gastrointestinal symptoms, where quinine cannot be given by the mouth, or in young children and fat patients where intravenous injections cannot be given because the veins are difficult to find. It is true that hundreds of injections may be given without untoward effects, but the very next one may lead to disaster. Necrosis of the tissues is often a slow process and the results may not be apparent until weeks or months after the injections. Intramuscular injections do not produce cinchonism on account of the slow absorption of quinine.

Briefly stated, the dangers of intramuscular injections are (1) tetanus, (2) necrosis and formation of an aseptic abscess and (3) injury to nerves.

Intravenous method. The indications for intravenous administration of quinine are firstly, appearance of a very large number of parasites in the blood such as a dozen or more in a single field and secondly, pernicious malaria with nervous or mental symptoms such as drowsiness, aphasia and nervous twitchings.

Two methods for giving intravenous injection of quinine are recommended :—

(1) By giving it in 8 to 10 ounces (200-300 c.cm.) of saline. The apparatus for injection consists of a tall glass funnel one inch in

diameter capable of holding 8 to 10 ounces of saline. To this 3 feet of rubber tubing is attached and at the end of this a sharp needle is fitted, such as that used for salvarsan injection. A thermometer for taking the temperature is also required. For injection, 10 to 15 grains of quinine bihydrochloride are dissolved in 8 ounces of normal saline, the temperature of the fluid being 110°F. , to allow for cooling during its course through the apparatus. Large quantities of saline used for dissolving quinine may however produce dilatation of the right heart, especially if given too rapidly and collapse or even death may result. On the other hand, if the injection is too concentrated it may produce inhibition of the heart's action, directly or through the central nervous system. Extensive experience has proved that the use of more than 100 c.cm. of fluid for each case, as advised by some, is unnecessary and not devoid of danger.

(2) Injections may be given by means of a 10 to 20 c.cm. syringe, $7\frac{1}{2}$ to 10 grains or more of the salt being dissolved in 10 to 20 c.cm. of sterile warm normal saline. Some clinicians dissolve 15 grains of the bihydrochloride in 5 c.cm. of normal saline, heat it to boiling point and draw up into a syringe and inject. One of the superficial veins at the bend of the elbow is selected for the injection and a clean puncture should be made with a sharp needle. The fluid is slowly injected, the needle pointing towards the shoulder; several minutes are taken to complete the injection. The most rigid antiseptic precautions should be observed.

The intravenous route is especially recommended in serious and dangerous malarial infections, *e.g.*, cerebral malaria, where we want the effect of the drug to be produced in a very short time and a few hours' delay would be fatal. One dose of 15 grains (1 gm.) is usually sufficient to stop the fever and to cause the disappearance of most of the parasites within 18 hours. The injection is repeated, if necessary, in 3 or 4 hours if by that time oral administration is not feasible. Many cases are lost owing to the hesitation on the part of practitioners in using this simple, quick and efficient method of controlling symptoms in grave cases. In chronic malaria when administration by the mouth fails to be effective, 4 or 6 intravenous injections may free the patient from parasites. It is important to give these injections so that they reach the heart in low concentration. Experiments on rabbits show that there is considerable difference in the minimal lethal dose of quinine, according as to whether it is given well diluted and slowly injected, or given

in concentrated form and injected rapidly. The minimum lethal dose by the latter method is much smaller.

The pulse should be carefully watched. If the injection is given too rapidly the pulse may become very feeble and alarming symptoms set in. Rigors sometimes appear within a few hours after injection; this is due to acidity of the salts, but it soon passes off. Some authorities advise the addition of a few drops of adrenalin solution to counteract the fall of blood pressure, but it seems to be unnecessary except in very severe cases of pernicious type. In some patients alarming symptoms appear in spite of all precautions. If the pulse becomes feeble give strophanthin or digitalin. If the injections are given slowly in a recumbent posture, the dangers of cardiac syncope are considerably reduced.

It has been demonstrated that large doses of ordinary quinine salts, *e.g.*, quinine hydrochloride, when given intravenously, are dangerous to life, the respiratory centre being more gravely affected than the cardiac centres. Acid hydrobromide in 15 grain (1 gm.) doses is less toxic to the respiratory centre than the acid hydrochloride and is preferred. Injections should be controlled by blood pressure observations especially in weak patients. It has been found, in experimental animals, that if intravenous injections are given continuously, circumscribed areas of necrosis appear in the adrenal cortex. Though the action of quinine injected direct into the blood stream is quicker than that of quinine given by the mouth or by the intramuscular method, it has no greater effect in destroying the gametocytes or eradicating the parasites from the body and so preventing relapses. Its action is more fleeting than when the drug is given by any other route, and for this reason, unless the administration of a dose is timed correctly in relation to the parasites, it is wise to supplement it as soon as possible by doses given orally. There is considerable evidence to show that quinine has little effect upon parasites contained in the red blood cells which are lying more or less stagnant in the small capillaries of the internal organs. It is chiefly effective against parasites which are free in the circulation, especially when carried to the peripheral parts of the body.

Acton and Knowles (1924) pointed out that the dangers of intravenous injections have been exaggerated. Phlebitis and thrombosis very rarely occur. Air embolism is a bogey; if proper care is taken $7\frac{1}{2}$ to 10 grains of acid hydrobromide in 15 to 20 c.cm. of sterile water is quite safe and can be conveniently given by a syringe. Larger quantities such as 15 grains in 5 c.cm. of saline (James) are not recommended as being too concentrated. It should be remembered that while the solubility of quinine hydrochloride is 1 in 35 of distilled water, it dissolves in 110 parts of Ringer's solution. About 90 per cent. of quinine injected disappears from the blood in a minute, and during that time it circulates in the blood in maximum concentration and has a destructive action on those parasites which have not reached the safe areas within the erythrocytes.

Cantlie and Mouharek (1924) in the Soudan treated a large number of cases of malaria by intravenous injections of quinine. They gave 9 grains of bihydrochloride, every day till the temperature became normal, as well as ten grain doses of bisulphate by the mouth. The injections occupied 30 to 45 seconds, the pulse was accelerated 5—17 beats per minute for not more than 3 minutes. Tingling in the mouth, ringing in the ears, sometimes constriction of the chest, rarely vomiting and on two occasions fainting occurred. Their observations showed that the action was more powerful and thereby the stay of the patient in hospital was cut short, but the relapse rate was 42.5 per cent. In another series of 1,103 cases there was a relapse rate of 77 per cent. after 6 to 8 injections in each case. A dose of 0.5 gm. of quinine given intravenously is as effective as 1.5 gm. by the mouth. If given on a fever-free day in benign tertian malaria, the paroxysm of the next day was cut short in 85 per cent. of cases against 64 per cent. with oral administration. Injections are also said to be effective in chronic malaria when administration by the mouth is not effective. Thrombosis of the vein often prevented the continued use of this method.

Intravenous injections of quinine should therefore be reserved for cases of special urgency such as cerebral malaria with delirium and coma, or malarial hyperpyrexia or malaria of pernicious type with persistent vomiting. They should be given

without hesitaton in such cases, and as soon as the condition of the patient allows it, oral administration should be started. Cordes (1928) treated 14 cases of cerebral malaria with $7\frac{1}{2}$ grains (0.5 gm.) of quinine in 10 c.cm. of water and saved all of them. In such cases puncture of the cisterna magna at the base of the brain and removal of 50 c.cm. of cerebro-spinal fluid is probably preferable to lumbar puncture. Cases with as many as 40 per cent. of the corpuscles parasitised, have been saved by injection of 15 grains of quinine daily for three days. Attention should be paid to the following points when giving intravenous injections :

(1) As they produce a fall of blood pressure and affect the respiratory centre, they must be given with the patient in the recumbent posture. (2) The injection must be a clean one into the lumen of the vein, otherwise it will produce necrosis and complications. If the needle misses the vein or slips out, stop the injection at once and before withdrawing the needle, suck back into the syringe all the solution that may have escaped into the tissues round the vein. (3) The injection must be given very slowly, at least 20 to 30 seconds being taken for the injection of each c.cm. (4) The solution should be freshly prepared.

The injections are followed by a transient feeling of dizziness lasting a few seconds while quinine can be tasted in the mouth before the injection is completed. It should be remembered that while intravenous quinine therapy is a useful addition in the treatment of critical attacks of malaria, it is useless in the prevention of critical attacks and in the prevention of relapses, and fails to rid the patient of parasites completely.

Intravenous administration of quinine should be given with caution when there is albuminuria, severe jaundice, organic disease of the heart, marked anæmia or debility and idiosyncrasy to the drug.

Summary. The best method of giving quinine is by the mouth and this is borne out by hæmatological as well as other evidence. It is best given in solution but owing to its very bitter taste vomiting may occur. Cachets are expensive but tablets if properly prepared are quickly absorbed after oral administration: they are convenient and cheap for routine treat-

ment, and for control of malaria on a large scale. Their therapeutic effects are not inferior. Subcutaneous injections find few advocates. Intramuscular injections should only be tried in those cases when the alimentary canal cannot tolerate quinine by the mouth. Under no circumstances should these latter be used for routine treatment of ordinary cases where quinine can be given by the oral route. Intravenous injections are preferable for severe and urgent cases, but as a routine treatment yield no better results than any other mode of administration. The physician treating the case will have to determine which is the best method to employ for the particular case.

As regards the time of administration of the alkaloid, we have already remarked that if quinine is given soon after a meal it hinders digestion by inhibiting the activity of the gastric and other ferments. It is advisable to give it $2\frac{1}{2}$ to 3 hours after a meal when the gastric contents are acid, the digestion has been completed and the stomach is nearly empty. If given at this time it rapidly mixes with the contents of the stomach and passes into the small intestine, from which it is rapidly absorbed into the circulation. There is also less liability of its producing irritation of the stomach which it undoubtedly does when given on an entirely empty stomach early in the morning or a long time after a meal. James prefers to give quinine 2 to 3 hours before the paroxysm of fever is due. Intramuscular injections may be given at any time, but it is preferable to give intravenous injections when the stomach is not loaded.

TREATMENT OF SPECIAL FORMS

Pernicious forms. The treatment of pernicious malaria should be started without a minute's delay. There are several types. In comatose or delirious forms the temperature may be normal or subnormal when the patient is first seen. In the bilious pernicious type vomiting is the chief symptom. In the intestinal form there is diarrhoea with bloody stools which on examination show malarial parasites in abundance. To save these patients, quinine in the form of the acid hydrobromide if possible, should be given at once by the intravenous route.

Cerebral malaria is the most fatal of all forms if immediate quinine treatment is not given. This condition is characterised either by sudden onset and rapid coma, or by hyperpyrexia, delirium, convulsions and other disturbances of the central nervous system. Early cases show symptoms of drowsiness, aphasia, nervous twitchings and a tendency to get out of bed. Alport (1919) recommended two intravenous injections of 15 to 20 grains during the first 12 hours combined with intramuscular injections of similar amounts in these cases. In semi-comatose, delirious and comatose cases he recommended even larger doses. It should however be remembered that large doses may damage the liver and the kidneys. The majority of cases met with in India can be controlled by giving one or two intravenous injections of 10 to 15 grains of quinine. In most of the critical cases one or two such intravenous injections given during the first 24 hours improve the condition of the patient and the temperature becomes normal. As soon as the patient is mentally clear an intramuscular injection may be given or quinine given by the mouth.

Chopra and his co-workers (1932) have shown that the first effect of intravenous injection of quinine often is to produce a definite increase in the number of parasites. When the infection is very heavy, e.g., when over 50 per cent. of the corpuscles are infected no anti-malarial remedy, by whatever route it is given, appears to be of any avail. The same thing is observed in monkey malaria in which quinine almost always fails when the blood of *M. mulatta* is heavily parasitised.

Post-malarial nervous manifestations such as tremors, myoclonus, hemicrania, also improve under quinine treatment. Neuritis and choreaform movements may occur in malarial subjects and clear up rapidly under quinine. Disturbance of the glycogenic function of the liver has been recorded in acute malaria and glycosuria may be produced; asthma-like attacks may occur; both these conditions improve rapidly under quinine treatment.

In cerebral malaria in which there is accumulation of parasites in the brain, inhalations of amyl nitrite have been recommended. The object is to dilate the cutaneous vessels and to make the parasites more accessible to quinine. In abdominal

forms adrenalin is given in combination with quinine. This constricts the vessels of the skeletal muscles and dilates those of the splanchnic area.

Quinine in induced malaria. Artificial infection of man with malaria has recently been employed for treatment of neurosyphilis. Two methods are employed for transferring the disease to the patient. (1) By inoculation of the malarial blood either subcutaneously or intravenously. This method is not recommended as in spite of all precautions the blood may contain a mixed infection and cerebral malaria may follow with fatal results. Another danger is the possibility of transmitting syphilitic organisms from one case to another. The incubation period is 5 to 30 days, but if intravenous injections of infected blood are given it is shortened, being only 4 to 8 days. (2) By means of infected mosquitoes, *A. maculipennis* being generally used in England. *P. falciparum* will not however develop in this mosquito at low temperatures. The incubation period in benign tertian infection is 14 days; *A. bifurcatus* has also been employed. The virulence of the infection varies in different individuals from very mild infection to such a severe reaction that death may occur even from benign tertian infection, unless daily examinations of the blood are made and quinine treatment initiated at the proper time. Another less easily avoided danger is fatal rupture of the spleen; this has been recorded after artificially induced malaria in man. It has been shown that infection produced by direct inoculation of blood is very easy to cure permanently with small doses such as 3 to 10 grains of quinine, and relapses are very rare, being only about 2 to 4 per cent. On the other hand in cases infected through the mosquito bite, relapses with the same dosage occur in over 56 per cent. of cases. Even with 30 grain doses of quinine daily for five days, James (1925) found a relapse rate of 25 per cent. It would appear at first sight that the sporozoites injected by these insects are more resistant to quinine than the trophozoites of red corpuscles of man, but it should be remembered that the vitality of most of the individuals who contract malaria under natural conditions is lowered. Even in these natural infections the result of quinine treatment has

been much better than in the residual resistant cases who were invalidated from Salonika during the Great War. There may be a small percentage of cases with exceptional resistance to quinine, but among thousands of artificially produced benign tertian infections, 40 to 50 per cent. clear up spontaneously, and the great majority of the remainder yield readily to short courses of quinine. The treatment of the general run of malaria cases in warm endemic areas with quinine is therefore very satisfactory, and disparaging views of the value of quinine in malaria derived from some of the post-war experiences are not justified when applied to the action of the drug in malaria under normal circumstances. The importance of early and adequate treatment in malarial infections is clearly brought out from the successful treatment of artificially induced malaria. If this is done, the development of resistant cases is prevented. There are very few cases who will prove resistant to quinine. In induced malaria, quinine must be given at once if more than 25 parasites are found in a field. It is not easy to correlate the course of the temperature with the stage of growth of the parasites. James (1931) treated 300 cases, certified under the Lunacy Act, of which 20 per cent. were discharged cured. Malaria was not cut down by quinine but was allowed to smoulder on. No quinine was given or if at all, it was just enough to control infection. Very few of these patients were infective to *A. maculipennis*.

Chronic malaria. After the acute symptoms have subsided quinine treatment should be continued if such symptoms as enlargement of the spleen and anæmia are present. Quinine has no effect on the crescents directly, but the drug will kill the young trophozoites, young schizonts and merozoites thus preventing the formation of crescents. If anæmia is present it is better to combine quinine with iron and arsenic. Some prefer to give intravenous injections of salvarsan and allied compounds instead of arsenic by the mouth, but the former treatment should only be reserved for special cases. In malarial cachexia small doses of quinine, combined with iron, arsenic and strychnine are the best.

Malaria complicated with pregnancy. Owing to the oxytocic properties of quinine, opinions have differed regarding its administration in pregnant women. It is now generally agreed that in malaria occurring in pregnancy, quinine must be administered and that the disease itself is far more likely to produce abortion than is quinine. Benign tertian malaria causes little trouble; but the malignant tertian infection is very liable to produce abortion, hæmorrhage and death. Quinine does not act as an oxytocic in malaria in pregnancy, provided labour has not already commenced. In some cases quinine can and does strengthen the normal uterine contractions of pregnancy, causing perceptible pains where labour has not commenced. (On the other hand quinine has been administered to many pregnant women, sometimes in fairly large doses, without causing untoward symptoms and pregnant women have taken quinine prophylactically for long periods, without showing any tendency to abort, provided they keep free from malaria. Cases have been known where the prompt administration of quinine has quietened the pains which had already commenced and abortion was threatened. Kadaner (1928) in the Congo found 0.3 to 0.5 gm. of quinine daily essential for the prevention of abortion in patients suffering from malaria. The blockage of the placental circulation by sporulating masses of the parasites may itself lead to the death of the fœtus and its expulsion. Congenital infection has been recorded by many observers and parasites have been actually found in the blood of an infant before the placenta is expelled, indicating transplacental infection. Infants frequently die of malaria within a few days of their birth in areas with a high malarial infection rate, and administration of quinine to the mother before delivery may avert this danger. In malarial subjects quinine should be given after child-birth to prevent the attack of fever which always follows parturition. Quinine at this stage is also further beneficial in increasing uterine contractions and thus aiding involution.

In pregnant women it is advisable to give smaller and divided doses of quinine more frequently rather than large doses less frequently. With large initial doses abortion may be

threatened but may not take place. Twenty grains intravenously have caused miscarriage in a case in four hours. Smaller doses such as 4 or 5 grains should therefore be given by the mouth every 4 hours until the patient receives 16 to 20 grains in 24 hours. This procedure decreases any chance of abortion in malarial fever. The preliminary purgative should not be omitted though in pregnancy it must necessarily be mild. A little bromide of potassium or opium may be combined with quinine, if necessary. In debilitated and anæmic individuals quinine acts more powerfully on the uterus, and in these persons greater care is required and smaller doses are to be preferred. The patients should lie in bed when the drug is being administered. In a large number of cases recorded, no ill-effects seem to have been produced even with such big doses as 30 grains in a day. Quinine given hypodermically is said to be more liable to produce abortion.

Quinine in children. Children tolerate quinine well and relatively larger doses may be given than are indicated by the age of the patient. The drug should be administered as soon as the diagnosis is made. In babies, it is advisable to give euquinine (quinine-ethyl-carbonate) or aristochin which is a tasteless powder. For a baby one year old, $1\frac{1}{2}$ grain every six hours should be given. For children of 3 to 5 years 5 grains of euquinine every six hours; for 5 to 10 years 7 grains of euquinine or 5 grains of sulphate or bishydrochloride may be given. In children under 10 years it is better not to give more than 5 grains of quinine in a single dose. The administration in children should be closely controlled by microscopic examination of the blood for parasites, when these disappear smaller doses should be given.

OTHER CINCHONA ALKALOIDS IN MALARIA

Quinine till quite recently has been employed in the treatment of all forms of malaria, but Acton has shown that while it cures 90 per cent. of malignant tertian infections if properly given, in the benign tertian infections the primary cures were not more than 18 to 30 per cent. even after a two months' course.

Cinchona febrifuge which contains all the alkaloids of cinchona bark gave a cure rate of about 50 per cent. so that it can be reasonably concluded that there must be alkaloids other than quinine, which are responsible for this enhanced rate of cures. These other alkaloids were tested individually. Cinchonine and quinidine in ten grain doses twice daily showed a cure rate of 60 per cent. of benign tertian infections after a short course of three weeks; these alkaloids were therefore preferred by him in these cases.

Fletcher recently tested the action of different cinchona alkaloids individually in the treatment of malaria; his conclusions are as follows:—

(1) In doses of 10 grains twice a day the 4 alkaloids, *i.e.*, quinine, quinidine, cinchonine and cinchonidine appear to be of equal value in bringing about the disappearance of malarial parasites in patients weighing 100 pounds.

(2) None of these alkaloids produce toxic symptoms when given in this quantity, not even cinchonine and quinidine.

(3) In doses of 5 grains twice daily, cinchonine does not appear to be quite so potent as quinine and quinidine.

(4) Cinchonidine sulphate is definitely inferior to other crystallisable alkaloids, when given in small doses.

(5) Quinidine sulphate acts better on the quartan parasites than quinine.

(6) Quinidine in 5 grain doses does not cause the disappearance of the parasites; in 10 grain doses it cannot be tolerated as it produces severe nausea, vomiting and collapse.

It would appear from this that there is little to choose between the different crystalline alkaloids of cinchona bark so far as their action on benign and malignant tertian parasites are concerned. Fletcher's conclusions regarding the toxicity of quinidine are not borne out by our experience. It is liable to produce depression of the heart, and fainting and sudden deaths have been known to occur, especially in those suffering from emaciating diseases such as kala-azar.

Dale and James (1925) found the curative effects of quinine, quinidine and cinchonine the same on all forms of malaria, and except for the depression caused by the last, there was no difference in toxicity. Ciuca (1925) made similar comparative tests with quinetum which is a form of cinchona febrifuge containing all the alkaloids but only 15 per cent. of quinine and 5 per cent. of quinidine. He found it to be as effective as pure quinine hydrochloride. In bird malaria the results with cinchonine, cinchonidine and quinidine ran closely parallel with those obtained in man. The Sergeants and Catnei (1925) found cinchonine and cinchonidine effective in removing malarial parasites from the blood and in reducing the size of the hypertrophied spleen; they found cinchonidine more powerful than cinchonine in splenomegaly. The Malaria Commission of the League of Nations (1927) stated that in doses of 1.0 gm. daily, quinine, quinidine and quinetum are equally efficient in producing a clinical cure in malaria. Cinchonidine in doses of 1.5 gm. equals the efficacy of other alkaloids.

It is evident from the above that much waste has resulted in using only pure quinine, and cheaper and equally efficacious alkaloids might well be substituted in the treatment of ordinary cases of malaria while the more expensive and refined alkaloids may be reserved for severe types of cases.

Quinidine. The data at present available are not sufficient to justify a definite pronouncement whether quinidine is in all respects an efficient and quite satisfactory substitute for quinine against malaria. It has been considered by some to be as prompt in its action against benign and malignant tertian as quinine and as well borne, while others did not consider it quite equal to quinine especially as regards preventing relapses; it was prone to cause more nausea. Fletcher (1925) considered quinidine as good as or even slightly better than quinine bisulphate in its effects. Sinton (1930) however thinks that quinidine has no more marked effect in producing a permanent cure in benign tertian malaria than has quinine. Quinidine is more expensive than quinine and has a more toxic action on the heart and this limits its use. Before prescribing it the heart should be carefully examined and the drug should be given in doses not bigger than 5 grains three times a day with citric acid. Fletcher found that in doses of 0.1 grain per

kilo. of body weight twice daily, it removed parasites from the peripheral blood as rapidly as similar doses of quinine.

Cinchonidine. Cinchonidine sulphate is the least toxic of all the cinchona alkaloids. Investigations of Fletcher and others have shown that in 10 grain doses twice daily, it is almost as effective against malaria as quinine and on account of its lower toxicity it is well borne.

Cinchonine. MacGilchrist (1916) and Silvestri (1921) considered cinchonine to be as effective against malaria as quinine; Acton (1920) thought it was the most toxic of all the cinchona alkaloids. Fletcher (1925) investigated its effect on behalf of the Medical Research Council and came to the following conclusions:—

(1) Cinchonine in doses of 0.1 grain per kilo. body weight is less efficacious than quinine in reducing fever, and in clearing malaria parasites from the peripheral blood.

(2) Cinchonine in doses of 0.1 grain per pound weight of body is as effective as quinine.

(3) Cinchonine is not more toxic than quinine.

Rogers (1917), Cuica and others (1925) found that cinchonine was slightly less efficient in removing the schizonts of benign tertian infection from the blood, and much less efficient in dealing with gametocytes.

Rogers (1918) recommended cinchonine bihydrochloride for intramuscular injections because it is more soluble than the corresponding quinine salts and therefore more rapidly absorbed. It is said to produce less injury to the muscle, is less painful, gives rise to less induration and is as effective as quinine against malaria. Because cinchonism is quickly produced by injection of this alkaloid it was thought that it was more rapidly absorbed than quinine which does not produce these symptoms so readily. He advised 10 to 15 grains daily in 1½ to 2 c.cm. of saline in the deltoid for four consecutive days, after which quinine is given by the mouth. Experiments by Acton and Chopra (1923) showed that there is no marked difference in the absorption of quinine and cinchonine after intramuscular injection and the damage to the tissues is about the same. The production of symptoms of cinchonism after its injection is due to the greater toxicity of the drug and not to its rapid absorption.

Quinoidine. This name has been given to the combined amorphous alkaloids which remain after all the crystallisable alkaloids have been

removed from an extract of cinchona bark. Opinions vary regarding their effectiveness against malaria. Prain (1902) and Waters (1916) found it to be as effective as quinine; Acton (1920) and Fletcher (1923) showed that it has no appreciable effect against malarial parasite in 5 grain doses twice daily. In 10 grain doses, three times daily, it was effective, but produced toxic symptoms, such as vomiting and diarrhoea. It is possible that the drug used by the two classes of workers was different or possibly the method of preparation now used renders the non-crystallisable residue less efficient. In any case, the results obtained do not seem sufficiently valuable in malaria to counteract the drawbacks of its toxicity.

From a perusal of the foregoing section, it will be seen that a good deal of confusion exists with regard to the cinchona alkaloids. The Commission of the League of Nations assisted by an expert Committee investigated the matter and came to the following conclusions (1932):—

(a) The name 'quinetum' should be reserved for a preparation consisting of quinine, cinchonidine and cinchonine in equal parts. If this preparation were made by extracting those alkaloids from the bark of *Cinchona succirubra* (which usually contains them in approximately equal quantities), only a small addition of one or other of the crystallisable alkaloids would be necessary in order to equalise the amount of each alkaloid in the preparation.

(b) Instead of continuing to use the name 'cinchona febrifuge' which in the past has been applied to alkaloidal mixtures of very different composition, it is suggested that a new standardised preparation containing all the alkaloids in cinchona bark should be recommended for general use in treating malarial populations, and that its name should replace the name 'cinchona febrifuge'. The new preparation should be standardised to contain not less than 70 per cent. of crystalline alkaloids, of which not less than 15 per cent. must be quinine. The amount of amorphous alkaloids must not exceed 20 per cent., mineral matter not more than 5 per cent. and water not more than 5 per cent. The name suggested for this new pre-

paration is 'totaquina.' The compositions (approximately) of available samples of the two types of Totaquina are as follows :—

		Type I, made by extracting the total alkaloids from cinchona bark	Type II, made by add- ing sufficient alkaloids to the residues of quinine manufacture.
		<i>C. succirubra.</i>	<i>C. robusta.</i>
		Per cent	Per cent.
Quinine	...	25·28	28·46
Cinchonine	...	27·67	16·00
Cinchonidine	...	84·18	47·58
Quinidine	...		
			7·10
			6·21
Total crystallisable alkaloids		87·08	92·0
			88·21
Amorphous alkaloids		8·86	8·70
Moisture	..	0·99	1·00
Ash	..	0·68	1·67
			10·47
			1·77
			2·18

It will be seen that, while the alkaloids in Type I are chiefly quinine and cinchonidine, the chief alkaloid in Type II is cinchonine. Also Type II contains quinidine, which is not present in Type I and it contains a larger amount of amorphous alkaloids.

On account of their different alkaloidal contents, the therapeutic properties of Types I and II must be considered separately.

Results of tests on bird malaria. Professor Giemsa has made toxicity and therapeutic tests of samples of each type in comparison with quinine and hydroquinine by the method of Roehl. The results showed that all the samples tested (three of Type I, one of Type II) were a little more toxic when injected intravenously into rabbits than hydrochloride of quinine administered in the same doses, and that, as regards their therapeutic action on the parasites of bird malaria (*P. relictum*), all of them were inferior to quinine. The sample which contained the largest amount of quinine (a preparation of Type I containing the total alkaloids of *C. robusta*) was the most active therapeutically, and of the two samples of Type I the preparation containing the total alkaloids of *C. succirubra* came next. The sample of Type II made from the residues of quinine manufacture and which contained less quinine but more cinchonine than any of the others was found to be least effective

therapeutically. Professor Giemsa concluded that the therapeutic action of the preparations was directly proportional to the amount of quinine which they contained.

Results of tests on human malaria. Tests on benign tertian malaria, *P. vivax*, intentionally induced by the bites of mosquitoes on ten individuals, were carried out at Horton under the direction of the Malaria Commission. Both types of totaquina were used. The composition of the samples tested is given below :—

			Type I (total alkaloids of <i>C. succirubra</i> .)	Type II (quinine residues.)
Quinine	38.4	15.8
Cinchonine	21.7	55.4
Cinchonidine	34.7	5.7
Quinidine	0.0	5.2
Amorphous alkaloids	5.8	18.4
Moisture	0.76	1.9
Ash	0.6	2.1
Total crystallisable alkaloids	94.8	81.6

The results are very much the same as those obtained by Professor Giemsa in tests on bird malaria. They may be summarized as follows:—

(1) One dose of 5 grains (0.3 gm.) of totaquina of either type has practically no effect on the fever or parasites. It is necessary therefore to use a single dose of 10 grains (0.6 gm.) for the test.

(2) A single dose of 10 grains of totaquina Type I produces the same effect in aborting the fever and in reducing the parasites as is produced by a single dose of 5 grains of quinine.

(3) A single dose of 10 grains of totaquina Type II has practically no effect in aborting the fever or in reducing the parasites. With this type of totaquina it is necessary to use a single dose of 20 grains (1.2 gm.) to produce the same effect as is produced by a single dose of 5 grains of quinine.

It appears from these results that totaquina Type I (total alkaloids of *C. succirubra* or *C. robusta*) when used in ordinary clinical therapeutic doses for curative purposes—*e.g.*, 1.2 gm.

(20 grains) daily for five to seven days—should give about the same good result as is given by quinine in the same doses. If this is so, and if this type of totaquina can be obtained more cheaply than quinine, it would be advantageous to use it for general purposes instead of the single alkaloid.

Cinchona febrifuge, it has been pointed out, is a mixture of all the cinchona alkaloids of the *C. succirubra* bark. Residual alkaloids are a mixture of the alkaloids precipitated from the mother liquor after most of the quinine in the bark of *C. ledgeriana* has been extracted. To this latter certain proportions of quinine sulphate are added and the mixture is used as a substitute for quinine. Both these products are cheaper than quinine and under the name of cinchona febrifuge have been used in the treatment of malaria in India with gratifying results. The following mixture is prescribed:—

Cinchona febrifuge	10 grains.
Citric acid	20 „
Magnesium sulphate	30 „
Peppermint water	1 ounce.

One ounce of this mixture is prescribed three times a day $2\frac{1}{2}$ hours after meals, for one week. It has been found quite effective, but it is liable to produce nausea and vomiting, as the amorphous alkaloids present stick to the mouth. The majority of patients, however, tolerate it well if it is taken at the right time, *i.e.*, $2\frac{1}{2}$ hours after food. If nausea and vomiting occur a dose of 15 minims of 1 in 1,000 adrenalin or a minim of tincture of iodine in a little water, before the cinchona febrifuge mixture is given, will check the vomiting. If necessary, 5 to 10 minims of tincture of opium may be given. Fletcher (1925) came to the conclusion that cinchona febrifuge with 7 to 10 per cent. of quinine is as efficient as quinine therapeutically in doses of 10 grains twice a day and it is no more toxic.

Derivatives of quinine and cupreine in malaria. Henry and Brown (1923) showed that the toxicity of quinine base is greater to the paramoecium than that of its salts. Quinine base is also effective in clearing the blood of malarial parasites in human patients. Insoluble salts of quinine such as quinine tannate, though tasteless, are not very effective against malaria. Euquinine (quinine-ethyl carbonate) is taste-

less and bulky, and it is effective in removing the parasites from the peripheral blood, as it is readily hydrolysed in the body to quinine itself. The hydroalkaloids such as hydroquinine hydrochloride, etc., are said by some to be more effective than quinine, by others less so. Cupreine sulphate in doses of 1 gm. was found by Giemsa and Werver (1914) to be a good substitute for quinine in human malaria, but it is expensive and toxic. These observers also obtained good results with quinethyline and quinpropyline, in doses of 0.3 to 0.4 gm. in human malaria and with these compounds and quinamyline in bird malaria. Ethylhydrocupreine or optochin has been tried in malaria with disappointing results.

CHAPTER XX

TOXIC EFFECTS

Quinine is one of the least toxic of the alkaloids, the lethal dose by the mouth in animals being 1.0 gm. per kilo. body weight. Frogs are killed by 1 mgm. per gramme by the mouth and by about half this amount given by injection. Pigeons are not killed by 3 gm. per kilo. by mouth although 0.5 gm. is fatal when given intramuscularly; rabbits are killed by 1.0 to 1.5 gm. by mouth, by 0.25 to 0.5 gm. subcutaneously and by 0.07 gm. intravenously. A dose given into the artery of a limb does not kill but causes complete paralysis of the part supplied by the artery. It is suggested that this action is due to paralysis of the leucocytes which plug the vessels of the limb, causing palsy. The fatal dose in man is 8 to 15 gm. by the mouth but in a few instances as much as 30 gm. has been taken without producing death. Two to three grammes can be tolerated but 5 gm. always produces toxic effects.

Toxic effects produced by cinchona alkaloids. There has been a tendency on the part of some clinicians to give large doses of quinine in the treatment of malaria. It should be remembered that the amount of this drug required to produce toxic effects varies enormously in different individuals. The solubility of the salt of the alkaloid employed, the vehicle in which the drug is given, the route of administration, the total quantity retained in the system, and the individual sensitiveness or idiosyncrasy of the patient to the drug, are some of the factors which play a part in all cases. In the majority of patients serious symptoms follow the administration of a total dose of 40 to 80 grains, while much smaller doses have produced toxic effects in sensitive individuals. Repetition of doses of quinine in patients who have suffered from cinchonism is not desirable.

The toxic effects produced by quinine can be discussed under the following headings:—

Quinine idiosyncrasy. Some individuals show very peculiar susceptibilities in regard to quinine, even when such minute quantities as 1/16 grain are given. The symptoms which manifest themselves are a variety of skin eruptions such as scarlatina-like erythema, urticarial rashes, intolerable itching or bullous eruptions, which may be accompanied by fever. Other symptoms are dyspnoea, fever, nausea and vomiting. Sometimes there are giddiness and fainting. There may be extravasation of blood in the skin and perhaps in the intestines and kidneys; occasionally there is severe prostration which disappears by the following day, but reappears some weeks later when the dose is repeated. In some cases itching of the skin and vesicular eruptions are produced by contact with quinine solutions. Sometimes cinchonine or quinidine does not produce idiosyncrasy in cases in which quinine does so, and so either may be substituted. Idiosyncrasy may suddenly appear in persons who formerly have taken large doses of quinine without any disagreeable consequences. It may also declare itself by occurrence of toxic symptoms after small doses (deafness, amblyopia, etc.) which are usually produced after large doses. This idiosyncrasy is not commonly met with in the tropics, where large doses such as 20 to 45 grains are given in 24 hours and it appears to be similar to that of potassium iodide in which idiosyncrasy is more commonly seen with small doses than with large ones. If the serum of a person suffering from idiosyncrasy to quinine is injected intraperitoneally into a guinea-pig, the animal's susceptibility to quinine is greatly increased. Rarely, quinine produces a paradoxical or contrary action, producing an enormous rise of temperature accompanied by rigors instead of the expected fall. This phenomenon still remains unexplained.

In susceptible individuals local application of quinine solution (1 in 10 to 1 in 1000) to the scarified skin produces a marked reaction which is not given by normal individuals. This may be used as a harmless test for quinine idiosyncrasy. The skin reactivity may be met with in the case of some laevorotatory alkaloids, *e.g.*, cinchonidine, ethylhydrocupreine, etc., and more rarely in dextrorotatory isomers such as quinidine, cinchonine,

ethyl-hydrocupreidine. Sensitiveness to quinine is not congenital and does not exist in blood relations.

Desensitization. This has been proposed and tried successfully in some cases. The patient is given 5 mgm. of quinine bisulphate plus 0.5 gm. of sodium bicarbonate to start with, by the mouth. After 1½ hour 0.5 gm. of sodium bicarbonate and 0.1 gm. of quinine are given. The two doses of quinine are repeated daily, the desensitising dose being left at 5 mgm. and the second dose being increased by 0.1 gm. every day. Another plan is to give 0.5 to 1.0 c.cm. of adrenalin by injection, followed 20 minutes later by a small dose of quinine such as 0.05 gm. Next day the same injection of adrenalin is given, but the dose of quinine is increased.

Cinchonism. This name is given to the early symptoms, chiefly connected with the central nervous system, which appear when quinine or other cinchona alkaloids are given in large doses. This should be differentiated from idiosyncrasy which is a condition of increased susceptibility and which is brought on by very small doses. Some individuals, however, are much more liable to get cinchonism than others. The power of producing cinchonism varies with the different alkaloids, cinchonine being the most powerful, next comes quinine, then quinidine and lastly cinchonidine. The association between the symptoms of intoxication and high concentrations of the alkaloid circulating in blood is very striking. These early symptoms are nausea, vomiting, headache (due to cerebral congestion), ringing in ears, giddiness and disturbed vision (due to selective changes in the vessels of the eye and ear). Minor symptoms may be somewhat diminished by bromide salts.

When a toxic dose of quinine is taken, the first symptom is usually severe bursting headache, accompanied by loud roaring in the ears and deafness, which may be complete but is rarely permanent. There is loss of taste and smell, mental depression, photophobia, and later blindness, at first partial and then complete. With very large doses abdominal pains with nausea, diarrhoea, vomiting and general muscular weakness occur followed by difficulty of speech, confusion of ideas, somnolence, loss of consciousness, delirium, general paralysis, coma, at times

convulsions, and finally death from collapse. Chills and cold sweats are also common, the pulse is rapid and weak and the respirations shallow. Large doses paralyse first the brain and respiratory centre and later the heart. The medullary centres as a rule are not affected till very late, and patients may recover even after very large doses. Quinine amblyopia and amaurosis have already been referred to. Quinine also produces skin rashes. There may be erythema, urticarial weals, swelling of the tongue and face, œdema of the eyelids, a scaly condition of the skin and a generalised itching eruption. It may also cause hæmorrhage from the nose, uterus and kidneys.

Quinine albuminuria. A fact of great clinical interest is that when large quantities of quinine are passed through the kidneys, temporary albuminuria is produced. Ramsden found that the proportions of quinine excreted diminished when the dose of the drug exceeded 2 gm. by the mouth, and Nierenstein found that such a dose given orally or 1.2 gm. given intramuscularly, frequently produced albuminuria. The kidneys can excrete very large quantities of quinine and as much as 2.2 gm. have been recovered from the urine within a day. Quinine is usually excreted at a concentration of 600 mgm. per litre in the urine which is about sixty times its concentration in the blood. Repeated administration of quinine does not increase the power of the body to destroy the drug, for the same proportion is excreted after prolonged administration. According to Marchaux 9.75 per cent. of cases taking quinine have albumin in the urine. The dosage, mode of administration (intramuscular injections are more liable to produce it), diet, climate, etc., are all factors concerned. Sinton and Lal (1927) found that the incidence of albuminuria was much less when quinine treatment was combined with alkali than when quinine was given alone.

Apart from albuminuria produced by quinine, renal changes occur in malaria. From ancient times quartan fevers have been recognised to be the cause of nephritis. Giglioli (1932) has drawn attention to cases of sub-acute and chronic Bright's disease where symptoms develop with the appearance of the parasites in the blood and disappear on the administration of quinine.

Visceral degeneration. Cornwall (1920) showed degenerative changes in the suprarenals and the kidneys, and increased degeneration of the erythrocytes in the spleen after large doses of quinine in rabbits. That quinine has toxic effects on the liver has been experimentally proved. Intravenous injections of moderate doses in rabbits produce progressive degeneration of liver cells, which increases with the increase of dosage. Quinine has a certain amount of hæmolytic effect on the blood cells especially in high concentration. It modifies the response to other hæmolytic agents such as acid solutions.

Macht and Teagarden (1923) showed that quinine and quinidine are more toxic to rats exposed to sunlight or to a quartz lamp than to those kept in the dark. Exposure of quinine solution to ultra-violet light produces chemical changes which render it more toxic to paramœcia *in vitro* and also more effective in bird malaria (1920).

The toxic effects of the other cinchona alkaloids are similar to those produced by quinine, but they show important differences that might make them therapeutically less desirable. Cinchonine and cinchonidine in large doses produce tonic and clonic convulsions, the site of their action on the brain being located below the optic thalami. Quinidine has a stronger depressant and paralysing effect on the heart. Cupreine is about half as toxic as quinine. Cinchonine is more toxic than quinine and produces salivation, hallucination and epileptiform convulsions. It has little effect on the blood pressure.

The grave effects of cinchonism are only met with when the dose of quinine is increased beyond 40 to 60 grains a day. Such large doses were prescribed at one time by practitioners in India and were often continued for long periods. These undoubtedly do harm. As a rule a maximum dose of 20-30 grains per day, according to the weight of the patient, divided into 3 or 4 doses, are quite sufficient in an adult to control the fever. Such doses are quite safe and effective and as a rule cause no untoward symptoms. There is no particular point in giving very big doses by the mouth as the intravenous and intramuscular method can always be resorted to when there is doubt regarding its absorption from the gut.

A form of toxæmia occurs in patients taking large doses of quinine for prolonged periods. In the old days patients who had suffered from malarial fever were put on large doses of quinine for periods ranging from 1 to 3 months, and this condition was not infrequently met with. The patients looked pale and anæmic, they were listless, had no inclination to make any exertion and had lost their appetite for food. There was generally a jaundiced tinge about the conjunctiva and the temperature was usually subnormal. All these symptoms were put down as after-effects of malaria, but they were due to the action of quinine on the gastro-intestinal tract and other organs, because stoppage of the drug or decrease in the dose rapidly improved the condition. The toxic effects of quinine have been attributed by some to the formation of a body called quinotoxin which is formed by the action of free organic acids on quinine, and it is suggested that such conditions arise in the gut. It is however found that this substance has a very low toxicity and could not be responsible for these effects.

Treatment of cinchonism. Numerous drugs have been tried to obviate cinchonism, and of these caffeine given subcutaneously or intravenously shortly before the administration of quinine is the best. To relieve headache phenacetin has been tried but it may depress the heart. If nausea is present 20 to 30 grains of sodium bicarbonate in a tumblerful of hot water is useful. Bromide of quinine is said to produce fewer symptoms of cinchonism, and therefore quinine has often been prescribed with hydrobromic acid.

CHAPTER XXI

MODE OF ACTION IN MALARIA

Rationale of action of Cinchona alkaloids in malaria. The cinchona alkaloids have a remarkable action against malaria. They kill the parasites responsible for the disease without injury to the host. Before the parasites were discovered the action of quinine was ascribed to some influence on the nervous system. Many years ago Binz, from his experiments with quinine and protozoa, prophesied the discovery of an organism belonging to this order as being the cause of malarial fever. This prophecy was fulfilled when Laveran in 1880 discovered the plasmodium in the blood of patients. If blood containing parasites is examined on the warm stage of a microscope, in the presence of minute quantities of quinine, movements of the parasites are arrested; if however the drug is given by the mouth, three hours elapse before the endocorpuscular forms become immobile, granular and lose their affinities for certain stains. It has been found that quinine does not attack the parasite with equal virulence in all the stages of development. The asexual forms as a rule are much more vulnerable; the sexual forms of *P. falciparum* appears to be hardly touched. The action of cinchona alkaloids controlling attacks of malarial fever is not understood. There are many points in connection with directing the attack of these alkaloids upon the most vulnerable stage of the parasite, about which we have not sufficient knowledge. With regard to the parasite we should know in what part of the body sporulation occurs and how long before the fever it occurs and how long it lasts. Does it occur in positions where quinine can easily penetrate? How soon after administration by different methods will the alkaloids be present in the system where they are required, when will they produce their maximum effects and how long will they remain there? Some of these points are discussed below.

The concentrations of quinine in the blood attained after therapeutic doses are not sufficient to kill the malarial parasites by their direct action. Other factors therefore must come into play.

Ramsden, Lipkin and Whitley (1918) found that quinine was present in the blood in a strength of 1 in 100,000, seven hours after administration. In a number of human cases treated with intravenous injections no direct correlation was found to exist between the concentration of quinine in the blood and the disappearance of the parasites. From the blood, a certain amount, varying with the individual, but averaging about 40 per cent. of the total amount administered,

is eliminated by the kidneys within three to twenty-four hours. Very little passes out in the faeces unless there is diarrhoea. The balance is fixed in the tissues, more in some than in others. For example the adrenals fix a larger quantity in proportion to their weight than do the liver, spleen, kidneys or bone-marrow. It is apparent from these studies that quinine makes only a brief stay in the blood circulation, and is only present here in minute traces; the blood corpuscles taking up very little. Acton and King (1921) concluded that the distribution of quinine between plasma and corpuscles was about equal. The question is of some importance as the malarial parasites being intra-corpuscular, no drug should be used as a chemotherapeutic agent unless it readily penetrates the red cells.

The following concentrations of quinine were found in the blood by Acton and King after 15 grains were given on an empty stomach.

Quinine

Interval after administration. (hours.)		Concentration of quinine in blood	Amount in blood (mgm.)	Per cent. of the dose taken.
1	...	1 in 150,000	33	3.3
2	...	1 in 187,000	27	2.7
3	...	1 in 225,000	22	2.2

Hydroquinine

1	...	1 in 250,000	20	2.0
2	...	1 in 280,000	18	1.8

Morgenroth (1918) estimated the dilution of quinine as greater than 1 : 150,000. Hatcher and Gould (1927) could not detect the drug in a single specimen of blood taken from 12 patients (after an interval of 30 minutes in 7 cases and up to 2 days in others) after 14.5 gm. of the drug was given orally and intramuscularly. After intravenous injection, a concentration as great as 1 : 20,000 may be obtained but rapid elimination from the blood stream takes place. It is extremely difficult to bring the concentration in the blood up to 10 mgm. per litre, the highest figure, so far obtained experimentally being 16.6 mgm. which was associated with very severe symptoms of poisoning. Even this concentration maintained for 48 hours failed to effect a radical cure of benign tertian infection.

Malarial parasites are hæmosporidia and as far as is known live only in the red blood cells; they are not found in the plasma in a free condition or in the cells of the tissues.

The only occasion on which they are free is when the mature schizonts rupture and they attach themselves to fresh erythrocytes. It is possible that the cinchona alkaloids may destroy them in one of the following ways:—

(1) By making the erythrocytes distasteful for habitation of the parasite in the same way as *E. histolytica* will not ingest emetinised blood cells. The merozoites are in this way prevented from penetrating the red blood cells and perish because they are deprived of the only food they can live on.

(2) By parasiticidal action when the parasite is in the red cells. It has been said that the action is most marked on the youngest forms, less on the mature forms and very little on the gametocytes. Literature on the subject does not bear out the evidence that intra-corpuscular forms are any more vulnerable to quinine than the extra-corpuscular forms. Craig after careful study of the action of quinine on malarial parasites in fresh and stained specimens came to the conclusion that it affects the parasite injuriously in all stages in man except just prior to sporulation. Some of the recent work, however, throws doubt on the parasites being in the red corpuscles; there are some indications that they may lie on the surface.

(3) By the destruction of the merozoites when they are passing from one corpuscle to another. The sporulating body is not affected by quinine and sporulation occurs, but most of the spores are said to be destroyed by the drug in the blood plasma (Craig). The disappearance of the young forms indicates that they are the forms most vulnerable to the action of these alkaloids. Once the parasite gains entrance into the erythrocyte, probably schizogony can be completed in spite of quinine. This, however, is not the whole explanation, for if it were true, quinine would be much more efficacious during the time of sporulation.

(4) Morgenroth (1918) believed that malarial parasites are unable to enter red blood corpuscles which have been treated with quinine. It has been recently shown that quinine tends to condense on the surface of solutions, or at the interface, to such a degree that it forms a rigid film. If a tough film were formed on the blood corpuscles, this might protect

them mechanically against the entrance of the parasites. Bass (1921) suggested that quinine renders the erythrocytes permeable to the lytic action of the blood serum.

(5) By the formation of potent decomposition products in the body. It has been shown in the case of the organic arsenicals that the concentration required to kill the parasites outside the body appears much higher than the concentration which can be conceived to exist in the blood stream. This is attributed to their transformation into more effective compounds in the body. In the case of alkaloids like quinine, emetine, etc., the assumption of toxic transformation is so unsupported by the chemistry of these agents that it appears to be improbable. A substance named quinenine is formed from quinine by the action of the liver. Quinenine however has no action on the malarial parasites either in birds or in man. Quinine does not form any antimalarial compounds with the tissue on incubation. It appears probable that the parasitocidal effect is not a direct one.

Another characteristic of the cinchona alkaloids has been shown to be their property of interfering with certain enzyme reactions. This property of enzyme inhibition shows considerable selectivity which would be more consonant with the specificity of antimalarial action. This would then be conceived as interference with a metabolic process that is essential to the developmental cycle of the plasmodia.

It is quite possible that quinine acts mainly on the young forms in the course of their passage from one erythrocyte to another or when they are adherent to them or before they have actually penetrated into the red cells, *i.e.*, whilst the parasite is in contact with the alkaloids circulating in the plasma. Quinine and the other alkaloids of cinchona, even in high dilutions, inhibit the movements of malarial parasites and may even paralyse them. It is even possible that quinine may condense on the parasites and thus hinder their movements. This action may prevent the parasites from penetrating further into the red cells and thus deprive them of the only food they can live on.

The action of cinchona alkaloids on the gametes. Crep-
scent s appear suddenly in the peripheral blood on the 11th day

of disease, increase to a maximum and then decrease. The average duration of a crescent wave is 14 days, but crescents may persist for 66 to 128 days, when there are frequent relapses. Crescents are most plentiful in new cases and in relapses; and are fewer in number in chronic, latent and recrudescant malaria. In acute cases of malaria administration of quinine for short periods is said by some to favour the appearance of gametocytes in the peripheral blood. Two hypotheses have been advanced to account for this:—(1) That the administration of quinine expels the gametocytes from the deep viscera to the peripheral blood and (2) that it creates an environment which favours the development of increased numbers of gametocytes. According to others, quinine in the early stages does not increase but tends to inhibit crescent production.

The formation of resistant forms may be nature's method of self-preservation of the species and occurs in all forms of free-living unicellular organisms. When the environment is favourable so far as nutrition is concerned, multiplication takes place asexually; when the environment becomes unfavourable, the organism after conjugation assumes the cystic or resting stage until conditions are once more favourable for their asexual multiplication. On the other hand, many malariologists are now abandoning the view that crescent production is a response to unfavourable environment. Crescent production is at its maximum in infants and very young children who are extremely susceptible to malaria. Occasionally also, it may occur at the very beginning of an attack of subtertian malaria. When the gametocytes are present in the peripheral blood, the mosquitoes become infected.

The cinchona alkaloids have been shown to have little or no action on the gametocytes of malignant tertian parasites in the blood and only slight action on those of benign tertian. Administration of quinine however in doses of 20 to 30 grains a day reduces the number of crescents, probably by cutting off the source of supply by killing the asexual forms. According to James (1924) the development of gametocytes in all three species is not morphologically affected by quinine. The life of a red cell is said to be 30 days, though estimates

vary considerably; it follows therefore that crescents cannot live longer unless the dead red cells adhere to the crescents. Muhlen and Kirchbaum (1923) transmitted subtertian malaria through *A. maculipennis* to a fresh case, the donor at the time of infecting the mosquito being under the influence of quinine. It has also been shown that gametocytes developed under administration of quinine are viable. The gametocytes of malignant tertian type after administration of quinine will still be capable of infecting mosquitoes and spreading infection, although the patient himself may be freed from fever. On the other hand although quinine will not cure a benign tertian infection it will emasculate the benign gametocytes so that there is no risk of their passing on to others (Meyer and Wenyon). There is no other drug except plasmochin which has a direct action on the crescents and destroys them. Quinine in very low concentration stimulates metabolism and increases the rate of multiplication of parasites (Acton and Chopra 1927), but in the dilutions in which it circulates in the blood after therapeutic doses it decreases the rate of multiplication and therefore few merozoites will be formed.

Bass (1921) showed that quinine bihydrochloride in concentrations of 1 in 4,000 when incubated for 5 hours with the schizonts of *P. falciparum* may produce degeneration of the parasites. Direct action of quinine upon the plasmodia is however negatived by the observations made by Muhlen and Kirchbaum (1924) and later confirmed by other workers. It was shown that defibrinated tertian blood mixed with quinine hydrochloride in a strength of 1 in 5,000 still produced infection after 12 hours' exposure in patients suffering from general paralysis of the insane. The blood left for five hours in contact with 1 in 2,500 quinine hydrochloride will still infect these patients. Quinine given to the donor does not render the blood materially harmless to the recipient, and mosquitoes can be infected from the blood of patients taking quinine which shows that the action of quinine is indirect. Once the parasites enter the red blood corpuscles, they are not much affected by the action of quinine, and this is a point in favour of the paralytic theory of the merozoites. Clinicians know that when quinine is

administered after sporulation is completed, it does not prevent the next attack.

The mechanism of cure of malaria cannot, therefore, be by quinine acting directly on the parasites. Lipkin (1919) suggested that possibly a metabolite of quinine was the active agent. It has also been suggested that possibly an antigen from destroyed parasites stimulates immune-body production and helps to overcome the infection. Taliaferro, Krishnan and others have shown that the cells of the reticulo-endothelial system engulf and destroy the parasites directly and upon their number and functional efficiency depends the immunity in malaria.

Immunity production. One of the oldest theories of the production of cure, far older than Ehrlich's, was that remedies stimulate the resistance of the body cells in general, and so help them to overcome the disease or infection. This theory is vague and general, and so far as quinine is concerned, we know that it has so little effect on the tissue cells in general that it could scarcely be imagined to increase resistance. Moreover, the malarial invasion is so strictly confined to the red cells that general resistance would have little application. A more modern and definite version of the resistance theory is that the agents stimulate the production of immunising substances by the body cells. It would seem, however, that the effect of quinine is far too prompt to give opportunity for the manufacture of anti-bodies, which is rather a slow process. Another suggestion is that of the sensitisation of the parasites by the natural immune substances of the blood and tissues. The prompt action of quinine again suggests that the effect must concern the blood rather than the tissues. Besides, the failure of quinine, in reasonable concentration, to kill the parasites in the shed blood as shown by inoculation experiments, indicates that this is not the mechanism.

Yorke and Macfie (1924) believed that when quinine is given to a person with malarial infection, it destroys a large number of parasites but not all. A considerable amount of soluble antigen is set free and this provokes the tissues of the host to the formation of an immune body. The immune body when present in sufficient amount, destroys the remaining parasites, producing sterilisation of the infection and the cure of the patient. This is supported by the fact that it is very difficult to infect some people with injection of blood containing living parasites. If, for any reason, there is an insufficient production of the antibody, sterilisation does not take place and a relapse will occur. Auto-hæmotherapy, that is drawing of the patient's own blood and injecting it subcutaneously, has been suggested in the treatment of malaria, the idea being that the parasites present in the blood will

die and act in the same way as a vaccine does. Sometimes parasites though reacting to quinine, may become resistant to the immune body, with the result that constant relapses occur. James (1928) believed that quinine continued for too long after an attack may interfere with the formation of the immune body. Cierns (1937) concluded that it must be accepted that quinine acts directly on the malarial parasites to which it is anchored and which it poisons. It is incapable of manufacturing a specific immune body, but it is nevertheless possibly favoured by its presence. Ross (1927) showed that in malignant tertian infections the parasite-containing corpuscles are lysed by the action of quinine with the formation of bilirubin, the amount of which in the blood is thus temporarily increased; it falls to normal as the parasites disappear from the blood.

It would appear from the above that it is not quite clear as to how a specific drug like quinine destroys the malarial parasites and produces a cure of this disease. All the facts at our disposal show that the action of quinine is probably not a direct one on the malaria parasites.

CHAPTER XXII

PROPHYLAXIS AGAINST MALARIA

As the eradication of malaria from malarious districts is a very difficult matter, attention has been paid to the prevention of the disease in individuals. This problem can be considered under three headings:—

(1) **Measures concerned with infected persons.** The segregation or isolation of malarial patients has been suggested, but in practice it is difficult to carry out. The disinfection of infected persons with quinine is not practicable, though with the introduction of plasmoquin, it may prove possible in the future to control epidemic malaria by mass administration of plasmoquin as a 'crescenticide'. Wholesale cinchonisation of infected persons to kill the parasites in the human host and so prevent the mosquitoes from becoming infected has been suggested, but it is now known that it is very difficult to destroy the gametocytes of malignant tertian with quinine after they have appeared in the circulation. The best measures which can be adopted are as early and as thorough a treatment as possible with a view to destroying the quinine-susceptible or asexual forms and preventing, as far as possible, the production of quinine resistant or sexual forms. Plasmoquin destroys the sexual forms of malarial parasites and is more suited for this purpose. If the cases remain infective, screening should be tried so that mosquitoes do not come in contact with the infected individual. If mosquito-proof houses are not possible, use of mosquito nets may be practicable.

Anti-relapse measures are important and they can be divided into three groups. (a) Administration of cinchona alkaloids. Any of the methods of treatment already suggested may be employed. (b) General measures, such as avoidance of fatigue, too long exposure to heat or cold and anything which lowers body temperature and may bring about a relapse, should be advised. (c) Removal of the patient to a better climate if that is possible.

(2) **Measures concerned with the transmitting mosquitoes.** These consist of destroying the mosquito by means of insecticidal drugs. *Paris green* keeps down the number of mosquito larvæ and has been largely used.

(3) **Measures connected with the susceptible person.** These consist of avoiding exposure to infection, *e.g.*, by guarding against mosquito bites and by taking quinine as a prophylactic measure.

Quinine prophylaxis. By this is meant taking of quinine in such a manner, as to prevent attacks of malaria, not by quinine acting on the sporozoites, but by preventing the multiplication of the parasites into which sporozoites develop. It really means that the body will have quinine circulating in the blood in such a manner as to anticipate the first dose of sporozoites injected by the mosquito. It does not prevent infection, but cures an attack by killing the parasites after infection has taken place, or reduces the degree of infection to such an extent that an otherwise dangerous infection is rendered mild and comparatively a harmless one. The incubation period of malaria is 12 to 14 days. Administration of the drug before infection does not produce any effect. It may be that, in spite of quinine, sporozoites still enter the red blood corpuscles and that quinine acts by killing the early stages of the parasites in the erythrocytes or the trophozoites when they are liberated. York and Macfie (1924) showed that under experimental conditions 18 grains of quinine daily for 5 days before and 7 days after bites by infected anopheles failed to avert an attack of malaria, but if the drug was continued for 10 days after the insect bite the disease did not develop. This indicates that quinine has little effect on the injected sporozoites but acts on the asexual forms liberated from the red blood corpuscles. Weber noted that quinine given to a disinfected donor did not render his blood non-infective to susceptible recipients, showing thereby that the blood must have contained some parasites which resisted the action of the drug.

It has already been pointed out that quinine acts more readily on the gametocytes of the benign tertian parasite than on those of the malignant tertian and therefore mosquitoes are more

readily infected from malignant tertian cases taking quinine than from benign tertian cases. If however quinine is not administered, benign tertian cases much more readily infect mosquitoes than the malignant tertian cases. *Anopheles* mosquitoes have been infected by feeding on the blood of patients taking quinine, thus showing that the benign tertian gametocytes are not killed by the action of the drug. It would appear from this that as quinine does not affect the entrance of the parasites into the blood, nor the development of the sporozoites in the red blood corpuscles in the early stages, it cannot therefore be regarded literally as a prophylactic against malarial infection. The drug probably acts chiefly by paralysing the movements of the trophozoites. The Malaria Commission of the League of Nations (1927) pointed out that quinine taken over a sufficient period of time and in appropriate doses can often prevent the appearance of symptoms, thus enabling the organism to rid itself of the parasites. It is not possible to store up quinine in the body ready to attack the malarial parasites when they gain entrance into it. It is useless, therefore, to give quinine in the pre-epidemic period; a start should only be made when the risk of infection arises. There is thus no advantage in giving quinine as a prophylactic to people going to very malarious countries before their arrival there. In countries with comparatively low incidence where malaria is often of the benign type, the continued use of quinine as a preventive of malarial attacks has little place. In countries where most of the indigenous population is infected with malignant tertian parasites, it is probable that 5 to 10 grains of quinine taken daily will not prevent the patient from contracting malaria but will render the attack of malaria, when it supervenes, so mild that the patient can still remain on duty.

There has been a lot of difference of opinion, lately, regarding the employment of quinine as a prophylactic measure. As long ago as 1760 Europeans living in the Guinea coast used cinchona bark powders continuously during the rainy and unhealthy seasons. The advisability of this is supported by much modern experience, although of late years there has been a distinct feeling against the prophylactic use of quinine, chiefly

on account of the experience during the Great War. Alport (1919) found that in Salonika 15 grains of quinine twice weekly did not prevent the soldiers from getting infected with malaria. He says that to submit healthy individuals to treatment such as this for long periods makes prevention worse than cure. On the other hand good results are reported from prophylactic doses of quinine. In the Belgian Congo it was found that 15 grains of quinine twice a week rendered the infections mild and few, only 0.3 per cent. of the working days being lost. Even those taking quinine only once a week for a year had considerably less infection at the end than at the beginning of the period. In Liberia 1 gm. of quinine on Sunday and 1 gm. in the middle of the week practically stopped the occurrence of blackwater fever. In Algiers it was found that daily doses of quinine rendered the attack milder and minimised the danger of the infected person becoming a carrier. The usual causes of failure are connected with dosage, method of administration and the amount of responsible supervision.

Hodgson was the first to point out that the incidence of malaria was closely correlated with minimum wet bulb temperature and he noticed in Delhi that a marked increase in malaria occurred a fortnight after this temperature reached a certain limit, not exactly determined, but probably 18° to 20°C . This increase continued as long as this temperature was maintained, but if it rose above or fell below these limits, a fortnight later the incidence diminished. The reason why minimum temperature affects the incidence of malaria is that anopheles usually bite during the early part of the night and digestion of red blood cells takes place some hours later. Flagellation of the male gametocyte takes place in the presence of moisture and occurs at a temperature between 18 to 22°C ; temperatures above and below these points hinder flagellation and, therefore, fertilisation of female gametes does not take place and without this the female gametes of malarial parasites cannot undergo their extracorporeal cycle in the mosquito for the sporozoites to be transmitted to the host. The temperature of cold-blooded animals like mosquitoes corresponds approximately to the wet bulb thermometer. According to this view prophylactic quinine should be given with due regard to seasonal variations of the temperature. It should be given when infection begins, i.e., when the minimum wet bulb approaches the point when flagellation of male gamete commences, and stopped when this ceases."

The next important question is whether quinine for prophylactic purposes should be taken daily or intermittently and at what time it should be taken. Various methods of administering quinine prophylactically have been suggested:—

Koch gives 15 to 22.5 grains on two consecutive days at intervals of 8 to 11 days. This method is known as the long interval prophylaxis and is not considered safe. Plehn gives 7 to 8 grains every 4th and 5th or 5th and 6th day. This is known as the method of double prophylaxis. In India usually 10 grains are given twice a week on two consecutive days.

Hehir suggests 5 grains daily for six consecutive days in the week when malaria in a locality is of mild type; when it is moderately severe, 10 grains are also given on the 7th day. If malaria is of severe type or occurs in epidemic form, the doses are doubled, *i.e.*, 10 grains a day for 6 days and 20 grains on the 7th day. In children one grain of quinine or $1\frac{1}{2}$ grains of euquinine for every 3 years of age is sufficient. In all cases the dose is usually given in the evening. Some authorities have suggested 5 grains of quinine in solution about an hour before sunset and a second dose of 5 grains about midnight in places where a severe type of malaria prevails. Even such doses as suggested above may not ward off the paroxysms in some places where malaria is severe. When the numbers of infected anophelines are small, comparatively few sporozoites reach the blood. It has not been possible to ascertain the minimum quantity of quinine necessary to destroy the young trophozoites developed from these sporozoites, but we know by experience that the minimum dose in an ordinary endemic year would not be sufficient in an epidemic year or even in a year of high endemicity. A larger dose is required in the late autumn than in early summer or midsummer. Failure may be due to the fact that a heavy infection had taken place before the prophylaxis was started. The optimum prophylactic dose of quinine to keep all men free from a harmful number of parasites has not been ascertained. Quinine prophylaxis would be more effective if controlled by periodic blood examinations, because this may discover some infection nearing sporulation when curative doses of quinine have a value.

Some prefer quinine in the form of solution but tablets are much more convenient. Ramsden's experiments have shown that after a single dose of quinine the time of excretion is 4 to 8 hours but the elimination goes on for 24 to 48 hours; when a series of doses is taken complete elimination takes $7\frac{1}{2}$ days. From these facts one is justified in concluding that continuous doses are the best. As quinine is not fully eliminated from the body within 24 hours, the dose may be given every other day, but daily administration would be the best. It has been shown on a small scale, that 5 grains of quinine daily reduce the attacks by 20 per cent.; 10 grains daily by 56 per cent.; 15 grains a day by 70 to 80 per cent.; but even 15 grains a day will not always prevent malarial infection. When malarial infection has occurred and paroxysms are produced larger doses should be given.

A further interesting fact is that in countries like India benign tertian infections occur commonly at the beginning and malignant tertian at the end of the hot weather, extending well into the winter months—November and December. This is due to the fact that infected anophelines are on the wing for weeks after their breeding season. To obtain the best results, therefore, prophylactic doses of quinine will have to be given practically all the year round with the exception of two or three months in the winter. It might appear from this that other preventive measures such as mosquito-proof houses, the use of mosquito nets, electric fans, well-built freely ventilated houses and proper drainage would be preferable wherever possible.

It has been stated that those habitually taking small doses of quinine as a prophylactic are very difficult to treat when they get infected, as the parasites become quinine resistant and in these people the disease becomes chronic. It has already been said that resistance of parasites to quinine is not probable. Chronic malaria, as a rule, does not develop when prophylactic quinine is being taken. Infection probably occurs from the lowering of the resistance of the individual and the dose which stops the paroxysms when the patient is strong will not do so when his vitality is enfeebled. It is necessary to increase the dose when such factors as fatigue, hardship and exposure, which lessen the resisting power of the individual, are encountered. Rigid adherence to one particular dose, *e.g.*, 10 grains twice a week, when the disease is of a virulent type accounts for failure of prophylaxis. Prophylactic dose of quinine which will prevent attacks in an individual with some degree of immunity will not be sufficient in case of non-immune fresh arrivals. This is borne out by the experience of Military Medical Officers in the Indian cantonments where the arrival of non-immunes may greatly intensify the endemicity of the whole area. They get the infection first and then infect anophelines in large numbers, thus establishing a vicious circle which is only broken when immunity is developed in the new-comers. The Report of the Malaria Commission

of the League of Nations has stressed the importance of the production of epidemics by immigrants who have no immunity against malarial infections.

Eradication of malaria from a large population was tried in Formosa with a certain degree of success by giving all the infected persons a thirty day course of quinine. In Switzerland and Corsica, extensive quininisation of the population has reduced the incidence of malaria in many districts. In the Dutch East Indies quininisation of the population has been tried, especially in the schools. In Palestine regular administration of 30 grains daily for 5 days, followed by 10 grains daily until the end of the malarial season, reduced the loss of working days to one-sixth. Even after prolonged quininisation one-fourth of the patients had parasites in the blood within four days of ceasing quinine, showing that the infection was merely masked and not eradicated. Quinine prophylaxis, unless associated with the destruction of anopheline mosquitoes, will not render an area entirely free from malarial infection.

Briefly then, the position of the prophylactic use of quinine against malaria is as follows:—Prolonged prophylactic use of quinine is a curative rather than a preventive measure. The dose should be sufficient to kill all parasites which develop in the blood from day to day. On the sporozoites it has no effect, and it only acts on the trophozoites when they are liberated from the red blood cells. It is advisable to take it in doses of 5 grains or better $7\frac{1}{2}$ to 10 grains daily in those areas where a large proportion of the indigenous population is infected with malignant tertian parasites, as in tropical Africa; this is the only sure way of averting attacks of pernicious malaria. Large doses may be necessary where a severe type of malaria prevails or an epidemic is present. On the other hand, in countries with comparatively low incidence, mainly of benign tertian type, the continued use of quinine as a preventive of serious malarial attacks will find little place in the so-called prophylaxis against the disease. Although quinine is no absolute protection against infection, it renders the attacks milder and less frequent and it lowers the mortality rate and spread of infection. The degree of success of prophylactic use of quinine depends on the control and distribution of the drug. Although malaria cannot be eradicated it can be kept under control by continued use of protective measures, as in the Panama-Canal Zone.

CHAPTER XXIII

QUININE IN BLACKWATER FEVER AND OTHER AFFECTIONS

Blackwater fever. Although the ætiology of blackwater fever is still undecided there is general agreement that malignant tertian malaria is always associated as a predisposing cause. It is a complication of malaria, occurring mostly in hyperendemic areas. Blackwater fever occurs in Central Europe, from Spain to the Balkans; in Turkey and Palestine; in such malarious parts of India as Assam, Bengal and the Dooars; throughout the tropical and sub-tropical parts of Africa from Algeria to Abyssinia and Rhodesia, Mauritius, Madagascar, the Southern United States, the West Indies and South America. The disease is very rare in mountains, but is common in the country and forest areas. It tends to recur in the same houses when they are near the breeding grounds of anophelines. Malarial parasites occur in over 73 per cent. of cases, generally *P. falciparum* is present but the infection may be mixed. *P. vivax* and occasionally *P. malariae* have also been found. One attack of blackwater fever predisposes to another attack so that as many as 13 attacks have been recorded but without any tendency to increased severity of the later attacks. Spirochaetes are said to have been found in the blood; but this has not been confirmed. The simplest and most widely held theory about its causation is that as the result of repeated destruction of red blood corpuscles owing to recurrent attacks of malaria, a hæmolysin is formed and hæmolysis is produced in the same way as by the injection of foreign blood into animals. It is asserted that the products of chemical changes brought about in the corpuscles due to the presence of the plasmodia act like a foreign material. The destruction of the red blood corpuscles occurs in the kidneys and probably in the peripheral blood as well. No hæmolysin has however been demonstrated in the blood.

The disease commences with a definite rigor and passage of dark urine, which may last several hours or several days. The blood shows marked anæmia, polychromasia and punctate basophilia. The large mononuclear cells increase to 20 per cent. or more and there is a marked shift to the left of the Arneth index. The spleen is enlarged soft and pigmented; the kidneys are enlarged, deeply pigmented with dark granular casts and degeneration of epithelium of the convoluted tubules; the heart shows fatty degeneration.

In India blackwater fever appears to be always associated with four pre-determining factors, *viz.*—

(i) The presence within half a mile of an aboriginal population saturated with malaria. This aboriginal population has become immune or tolerant to the infection, but the malaria strain concerned is one of intense virulence. The aborigines themselves do not get blackwater fever.

(ii) The disease attacks only the susceptible immigrants, such as Europeans, Chinese carpenters, Bengali clerks, and their families.

(iii) The presence of anophelines of the *funestus* group.

(iv) Usually, but not necessarily always, the irregular taking of quinine over considerable periods. Blackwater, however, is not always and inevitably associated with taking quinine. In the monkey *Silenus trus* inoculated with the monkey plasmodium *Plasmodium knowlesi*, blackwater occurs as a terminal event in the fever, in the absence of any quinine administration. This is probably due to the terrific intensity of the infection in this species of monkey.

Many poisons are known which attack the blood corpuscles and destroy them. Quinine, in concentrations in which it occurs in the blood does not destroy red cells, and yet many authorities have laid stress on its association with this disease. Neither clinical history nor animal experiments tend to show that quinine is the cause of it. Blackwater fever was known to exist in Europe long before quinine was introduced. Bi-hydrochloride of quinine has a hæmolytic action on the erythrocytes, but during life it is not possible to reach a sufficiently high concentration in the blood to produce it. Some observers think that quinine produces hæmolysis by lowering the osmotic pressure of the plasma, which causes water to pass into the red blood corpuscles which swell up and burst. Nierenstein (1919) isolated a derivative of quinine, hæmoquinic acid, from the urine of cases of blackwater fever. Manson pointed out that hæmoglobinuria could be produced in certain cases by the administration of a single dose of quinine. An instance has been recorded of seven consecutive attacks of hæmoglobinuria in the same individual, each attack being a sequel to a dose of quinine. Such small doses as 5 grains by the mouth

brought on an attack. Such cases do not necessarily show increased vulnerability of the red cells to the hæmolytic action of quinine *in vitro*. No evidence of any hæmolysin in the peripheral blood has been found by some workers while Chiron (1927) claimed to have demonstrated its presence. Manson-Bahr and Sayer suggest that quinine may possibly excite blackwater fever by inducing a sudden contraction of the spleen which expels hæmolytic toxin into circulation. Garrod regards cold as a most potent factor in its production in patients suffering from malignant tertian infection and considers that quinine is not essential in causing an attack, but is a contributory factor. According to him, patients treated with very large doses of quinine, are not more liable to an attack. Increase of lactic acid in the blood owing to deficient oxygenation such as occurs in anæmia is suggested as the cause of hæmoglobinuria; lactic acid has a hæmolytic action on the blood *in vivo* and *in vitro*. It is also suggested by him that in the presence of bile, quinine becomes highly hæmolytic and some undetermined constituent of the bile renders quinine hæmolytic in one-tenth of the concentration usually required. Disturbed function of the liver has been put down as the cause of blackwater fever. Kessler (1925) showed that lecithin increases the hæmolytic action of quinine on the blood *in vitro*. It has also been shown that in blackwater fever the degree of bilirubinæmia is much greater than in uncomplicated malignant tertian malaria. It is assumed that some such substance is liberated in the blood by repeated attacks of malaria and produces the symptoms. Other authorities have suggested that the presence of a foreign protein resulting from destruction of merozoites, induces an anaphylactic phenomenon. But blackwater fever has nothing in common with anaphylaxis. Hyperactivity of the reticulo-endothelial system, due to repeated attacks of malaria with consequent hæmoglobinuria, is another theory. It is now recognised that proper administration of quinine prevents the occurrence of blackwater fever; but once an individual is predisposed to blackwater fever by repeated attacks of neglected malaria, full doses of quinine may act as an exciting cause in precipitating hæmoglobinuria.

The causation of this condition has been thought to be:—

- (1) An underlying condition of a very chronic malarial infection. This is not the entire reason as otherwise it would be more commonly met with; besides it is quite safe to give quinine in malarial cachexias without causing hæmoglobinuria. In certain districts of the Punjab where malarial conditions are ideal as regards malignant tertian infections, no hæmoglobinuria is met with. The disease is however limited to areas in which malaria occurs not only endemically but in

severe forms. During or preceding the attacks, malarial parasites are frequently found in a large number of cases and there is a relative increase of the large mononuclears with increase of pigment in the corpuscles. (2) Some undiscovered specific poison, like that causing 'Texas red-water fever' in cattle (*Piroplasma bigeminum*). (3) A form of quinine poisoning. Administration of quinine could only be the determining cause in those cases which have an idiosyncrasy or intolerance for the drug. The condition of the blood in these individuals is such as to foster the destruction of the red blood cells. Apart from quinine intolerance, that there is a critical exciting dose of quinine, varying in different individuals, which may bring about an attack in some cases, is very definite. It is believed that for certain patients there is a critical dose, in whom quantities smaller than that causing it should, therefore, be prescribed. If hæmoglobinuria occurs, administration of quinine should be immediately stopped. Some authorities believe that if alkalies such as bicarbonates are given with quinine treatment, blackwater fever does not occur.

From these considerations it will be seen that the whole subject requires further research. That both malarial hæmoglobinuria and quinine hæmoglobinuria exist is certain, but blackwater fever may be a specific disease due probably to some such organism as a piroplasma. In the author's experience in British East Africa two groups of these cases were differentiated. (1) In which malarial parasites occurred in large numbers. (2) In which they were entirely absent, this was the more severe type producing a very high mortality. Quinine produced immediate good effect in the former class and also when the parasites reappeared after an attack, which is usually 5 to 14 days after cessation of hæmoglobinuria. In the second group of cases quinine had no effect. Whether this latter group was produced by any specific organism or whether it was a later stage of the first where all the parasites had disappeared from the blood, has not been determined. In ordinary cases administration of quinine after the attack does not lead to hæmoglobinuria, but if there is a history of predisposition to such an attack it should be given with great caution. The amount of

quinine which can be administered to these patients depends on the quantity of urine passed in 24 hours, because if the kidneys are unable to excrete a sufficient amount of urine to get rid of the quinine, it accumulates in the body and gives rise to symptoms of quinine poisoning such as amaurosis. Caution should therefore be exercised, especially in the acute stages of the disease when it is necessary on the one hand to destroy the malarial parasites, and on the other hand to see that the quinine is being excreted through the kidneys. Quinine acts first on the infected red corpuscles and hæmolyses them so that the parasites disappear from the peripheral blood. It is better to start with small doses, *e.g.*, 1 to 2 grains several times a day and only to increase them when it is clear that the drug is being well tolerated, for occasionally even with such small doses hæmolysis may occur. Administration of large doses of alkali with quinine is beneficial. Whenever malarial parasites are found to be present in blood, quinine should be given at once. This occurs 5 to 14 days after the urine has cleared, and it has been shown that parasites may be found in the internal organs in fatal cases after death, and yet may be absent in the peripheral blood during life. The prophylactic use of quinine in endemic areas, though it does not prevent infections, stops their becoming severe or pernicious, and by maintaining health acts as a true prophylactic against blackwater fever. Plasmochin has been tried with success in a number of cases of blackwater fever.

As regards the general treatment of these cases the patient should be put to bed at once and should not be allowed to sit up as there is danger of sudden heart failure ; absolute rest is essential. When the urine tends to be suppressed caffeine citrate 2 grains twice daily may be given as a non-irritating diuretic. The patient should have plenty of bland fluid and an exclusive milk diet until the urine is free from albumin. Hot fomentations over the loins or dry cupping may be useful. High rectal lavage with hot water has a diuretic effect. Hypertonic saline containing 120 grains of sodium chloride and 4 grains of calcium chloride in a pint of sterile water is recommended. If vomiting is present give enemata of 6 to 8 ounces of warm saline

and also saline subcutaneously. Five grammes of sodium bicarbonate in a tumblerful of hot water should be taken frequently. If there are convulsions, give 5 per cent. solution of glucose in 1-2 pints of saline intravenously. In case of restlessness give $\frac{1}{4}$ grain of morphine. Injection of antivenomous and other serums has been recommended. Activated horse serum is also useful. Iron and arsenic should be prescribed during convalescence. Recently, cholesterinated oil has been recommended in the treatment of this condition.

QUININE IN OTHER CONDITIONS

Pneumonia. Quinine was used in the treatment of pneumonia for over half a century ago. Aufrecht (1915) claimed that quinine has a specific action in pneumonia and by its consistent use mortality could be reduced. Boecker (1921) found strikingly large quantities of quinine in the lungs and in the expectoration of consumptives after its administration by the mouth. The pneumonic lung 4 days after injection, still contains quinine in higher concentration than is ever found in the blood. Statistics have been compiled to show that the mortality in the patients treated with quinine is much lower than those not treated with this alkaloid. Quinine should be given as early in the disease as possible. Continuous treatment with small doses every 2 or 3 hours is the best. It is inimical to the progress of most acute infections and in the case of pneumonia it is said to limit the spread of consolidation, thus altering the whole aspect of the disease. Calomel should be given to clear the bowels, and quinine may be combined with such an aperient as sodium sulphate. Intramuscular injections of quinine hydrochloride 0.50 gm., urethane 0.25 gm. and water 5.0 c.cm. have been recommended. This solution can be boiled. The patient is given an injection at once on the day of admission, one on the following day and afterwards every second day, but as a rule not more than four injections are necessary. Quinine in pneumonia finds no place now in practical therapeutics.

Common cold and influenza. Quinine is often used in the treatment of the common cold. It cannot reach the mucous membrane in strengths sufficient to produce antiseptic effects but it probably acts as a sedative. It has also been tried in influenza as a prophylactic, and for treatment in doses of 0.3 gm. once or twice a day.

Puerperal septicaemia and other conditions. Puerperal septicaemia has been treated with 2 grains of quinine every few hours. Quinine has also been used in any form of suppuration in the body *e.g.*, perityphlitic abscess, gall bladder abscess, empyema, bone and

joint disease. Prior to and immediately after operation. It is also recommended in erysipelas.

Exophthalmic goitre. Quinine and cinchona alkaloids are useful in this condition because of their vaso-constrictor properties on some vessels and secondly because of their effect on the heart. Besides this quinine retards all vital processes, it inhibits the conversion of glycogen into sugar and also limits protein metabolism. For this reason it has a beneficial effect in this disease where, owing to increased activity of the thyroid, the metabolism is markedly accelerated. A dose of 0.8 gm. of quinine is given in two portions and increased gradually every day. As soon as tinnitus begins the patient goes to bed. The alkaloid is continued for 8 days after which there is a rest for 8 days. This is repeated until the clinical symptoms, *e.g.*, pulse, exophthalmos, etc., improve. Quinine is subsequently given for three days in the week. The effect of quinine is said to be strengthened by combining it with 30 minims of extract of ergot

Diseases of the circulatory system. Quinine has had the reputation for being a cardiac sedative for a long time. Upolzer considers that along with rest and digitalis it is one of the three most powerful therapeutic agents in heart disease. It is said to have a damping effect on excessive digitalis action and is therefore often combined with it. It is claimed that a mixture of digitalis and quinine produces better effects than digitalis alone. Quinine and quinidine have a powerful action in controlling cardiac arrhythmia and irregularities. These should however be used with great caution when there is true weakness owing to myocardial disease.

Other conditions. In lumbago, injections of quinine-urea-hydrochloride relieve pain. In the treatment of sciatica, injections of quinine-urea-hydrochloride into or about the sciatic nerve are recommended. One per cent. solution is generally used and 15 to 30 c.cm. are injected at the point where the nerve lies over the neck of femur. The patient lies on the unaffected side with the affected thigh half-flexed. A point is selected somewhat lateral from the midpoint. The needle is pushed in for 3 to 4 inches and when it strikes the nerve a smarting pain is felt down the leg.

On account of its diuretic effect it is said to be very useful in certain forms of cedema and dropsy, especially those due to anæmia and cachectic conditions.

Quinine in 1 to 2 grain doses has been used with beneficial results in cases of vertigo combined with migraine. *Hæmorrhoids* have been treated by injections of a 5 to 10 per cent. solution of quinine-urea-hydrochloride. A perivenous sclerosis is said to be produced which progressively constricts the veins. The injections are entirely painless.

In the treatment of *varicose veins* intravenous injections of quinine into the local veins are employed. The drug acts (1) by reducing the

time of coagulation of blood and (2) by irritating the wall of the vein and producing thrombi which become firmly attached to the vessel. The solution recommended is quinine hydrochloride 0.40 gm., urethane 0.20 gm. and distilled water 3 c.cm. One to 3 c.cm. of this are given locally into the varicose veins.

Pruritis ani, vulvæ and scroti have been treated by infiltration of the skin and subcutaneous tissue with 0.25 to 0.5 per cent. quinine urea hydrochloride. Itching is at once arrested and excoriations rapidly healed. One injection may suffice to keep down the condition for months. As much as 100 to 200 c.cm. of the solution may be necessary.

Venereal diseases. Quinine has been used as a prophylactic against contracting venereal diseases, because of its bactericidal action on the gonococci and spirocheticidal action. It is often combined with calomel and gelatine in a strength of 2.5 to 15 per cent.

Induction of labour with quinine. Quinine has been used for many years as a means of re-enforcing uterine contractions, especially when they are not strong. Most authorities agree that in therapeutic doses it does not excite the activity of the quiescent gravid uterus and therefore, it cannot be relied on for inducing premature labour. If however weak contractions are present they are intensified. The greater the tone and activity of the uterus the more rapid is the action of quinine. It is considered by some to be safer and its action more persistent than pituitrin. Various methods of giving quinine have been adopted.

Watson's method. Castor oil one ounce at 6 p.m., quinine hydrochloride 10 grains at 7 p.m., enema at 8 p.m., quinine hydrochloride 10 grains at 9 p.m., and again at midnight. If labour pains do not start by 7 a.m., on the next day, give $\frac{1}{2}$ c.cm. of pituitrin intramuscularly and repeat every half an hour till labour commences. Balley (1926) recommends 2 ounces of castor oil to start with, and an hour after, $\frac{1}{2}$ an ounce of quinine mixture containing 10 grains to the ounce. After one hour a simple enema is given. Two hours after the enema another dose of the mixture is given, this is repeated after 3 hours and then four hours later, making a total of 40 grains of quinine. The percentage of success with this treatment is greater than with pituitrin and the danger is less.

Quinine as a contraceptive. Quinine has been used as a contraceptive in clinical practice for a long time but during recent years it has been replaced by other drugs.

CHAPTER XXIV

PREPARATIONS OF CINCHONA BARK AND ITS ALKALOIDS

Cinchona Bark, dose 5 to 15 grains. **Extract cinchona** (contains 10 per cent. total alkaloids) dose 2 to 8 grains. **Extract cinchona liquid** (contains $\frac{1}{2}$ gr. of the alkaloids in 15 minims). Dose 5 to 15 minims. **Compound tincture of cinchona** (contains 0.5 per cent. of total alkaloids), dose $\frac{1}{2}$ to 1 drachm (2 to 4 c.cm.). **Cinchona febrifuge** is a mixture of the total alkaloids of cinchona bark of varying composition. It has been extensively used in India for the last 50 years with satisfactory results. It is cheap and suitable for mass treatment. It has recently been standardised by the Malaria Commission of the League of Nations.

Totaquina. A mixture of the alkaloids from the bark of *Cinchona succirubra* and other species of cinchona. It contains not less than 70 per cent. of crystallisable cinchona alkaloids, of which not less than $\frac{1}{5}$ th is quinine. Dose 1 to 10 grains.

CINCHONA ALKALOIDS AND THEIR PREPARATIONS

A. Crystalline alkaloids.

Quinine hydrobromide occurs in white acicular crystals, soluble 1 in 40 of water and contains 76.6 per cent. of quinine. It is said to lessen cinchonism and is valuable in acute rheumatism. Dose 5 to 15 gr. **Quinine bihydrobromide** contains 60 per cent. of quinine, soluble 1 in 7 of water and is suitable for subcutaneous and intravenous injections. It is non-irritating and the additional hydrobromic radicle tends to prevent cinchonism. Dose 5 to 10 grains.

Quinine hydrochloride contains 81.7 per cent. of base. Solubility 1 in 32 of water and in 1 in 2 of 90 per cent. alcohol; used for subcutaneous injections. Dose 1 to 10 gr. It is mixed with theobroma oil and forms a part of many contraceptive preparations. Quinine hydrochloride is contained in **Tincture quinine**, the dose of which is $\frac{1}{2}$ to 1 drachm and **Vinum quinine**, dose $\frac{1}{2}$ to 1 ounce.

Quinine bihydrochloride contains 81.6 per cent. of quinine; solubility 1 in 0.6 of water. It is considered a good salt for intramuscular and intravenous injections; the hydrochloride radicle is also not as irritating as the sulphuric radicle to the stomach. Dose 1 to 10 gr. For intravenous injections some use 1 to 300 solution, others 10 per cent. solution. Half to 1 per cent. produces local anaesthesia when

injected; for painting on mucous membrane 10 per cent. solution is the best. Sterules of various sizes are on the market.

Quinine hydrochloro-carbamide or urea-quinine occurs in small prisms; solubility 1 in 1 of water, contains 59.2 per cent. of quinine. Dose 5 to 15 gr. Used to produce local anæsthesia in 1 to 3 per cent. solutions; anæsthesia persists from 4 to 6 hours to several days.

Quinine hydriodide and **acid hydriodide**, **quinine hypophosphite** and **quinine lactate** are some of the salts which are not much used.

Quinine phosphate contains 72.8 per cent. of quinine base. Dose 1 to 6 gr.

Quinine salicylate occurs in white crystals; sparingly soluble in water; contains 68.8 per cent. of quinine base. Useful in sore throat.

Quinine acetyl salicylate contains 64.3 per cent. of quinine. It is a useful antipyretic and antiseptic compound. Dose 1 to 5 gr. It is prescribed in painful sore throat.

Quinine sulphate contains 73.5 per cent. of quinine base. Dose 1 to 15 gr. It occurs in white crystals, solubility 1 in 800 of water. It occurs in a number of preparations. **Ammoniated tincture of quinine** is a solution in 60 per cent. alcohol to which ammonia is added; the precipitate formed is suspended in tragacanth. **Quinine bisulphate**. Dose 1 to 10 gr.

Quinine tannate contains 30 to 35 per cent. of quinine base. It is tasteless and is recommended for children. Absorption is uncertain. It splits up slowly in the intestine and is therefore not prompt in its action. Dose $1\frac{1}{2}$ to 15 gr.

Quinine arsenate, dose $\frac{1}{4}$ to $\frac{1}{2}$ gr., occurs in small white crystals sparingly soluble in water; contains 15.2 per cent. of arsenic acid and 69.4 per cent. of quinine. **Quinine cacodylate** given *per os* and subcutaneously; dose $1\frac{1}{2}$ to 4 grains. **Quinine citrate**, dose 1 to 5 gr. **Iron and quinine citrate**, dose 5 to 15 gr.

Quinine ethylcarbonate or **euquinine** occurs in white needles having a melting point not below 95°C. It is sparingly soluble in water but is more so by addition of dilute acid, easily soluble in alcohol. It is practically tasteless. Eight grains of euquinine are equivalent to 5 grains of quinine sulphate. It is rapidly absorbed and appears in the urine soon after injection. Dose 3 to 16 grains.

Aristo-quinine or **aristochin** is insoluble in water and is tasteless. It contains 96.1 per cent. of quinine. Dose 1 to 10 gr. It has been used against malaria, influenza, and in small doses in pertussis.

Soloquinine is the name given to quinine salicylic ester.

Chenophenin is phenetidin-quinine-carbonic ester. Both these compounds exhibit the action of both the constituents of the drug. **Collobiase of Quinine** is a preparation in which quinine is kept in a colloidal state in combination with arabinic acid. It contains 30 per cent. of quinine base. It can be given intravenously and subcutaneously.

Collosool quinine or the alkaloid in colloidal condition has been introduced.

Tests for quinine.

1. *Fluorescence.* The alkaloid is dissolved in dilute sulphuric, acetic or tartaric acid (the test tubes should be made of transparent glass or silica). One mgm. of quinine can easily be detected in 4 c.cm. of solution. Fluorescence is visible in acid solution containing 1 in 200,000 of quinine. The fluorescence may be masked by the presence of chlorides and hence the test is not a very useful one.

2. *'Thalleoquin' reaction.* To 10 c.cm. of the solution of quinine add 3 c.cm. of chlorine water or 0.5 c.cm. of saturated bromine water. Shake well, and then add one drop of strong ammonia solution or sufficient to render the liquid distinctly alkaline. If the proportion of quinine exceeds about 1 per 1000, a green substance is precipitated. In more dilute solutions, a deep green colouration is produced. One in 5,000 quinine solution is detected by this test and if bromine is used instead of chlorine, quinine can be detected in a still higher dilution (1 in 20,000). This test is given by quinine, quinidine, and the hydroquinine alkaloids, and the decomposition products quinotoxin and quitenine. The cupreine series also give this test. It is not given by the members of the cinchonine series or their decomposition products. In 10 c.cm. of solution 0.25 mgm. of quinine can be detected with ease.

3. *Herapathite reaction* (Ramsden and Lipkin). (1) To 10 c.cm. of test solution add 5 gm. of $(\text{NH}_4)_2\text{SO}_4$, alkaline it with ammonia and extract the quinine by shaking it with three successive 5 c.cm. lots of purified ether. Transfer each lot of ether as it separates, into a small silica crucible on a water bath. (2) Dissolve the residue when quite dry in a minimum amount of anhydrous ether. (3) The ether solution is now transferred drop by drop on a warm microscopic slide so that the residue left by its evaporation is spread over a minimal area. (4) Put on a cover slip and add just enough of Christensen's reagent (Iodine, 1 gm.; 50 per cent. HI, 1 gm.; concentrated H_2SO_4 , 0.8 gm.; 70 per cent. alcohol, 50 gm.) to fill up about $\frac{2}{3}$ of the enclosed space and by gentle pressure bring it in contact with the residue left by the ether. If quinine be present blackening will be visible to the naked eye. Examine microscopically when golden green tablets or leaflet like crystals will be seen, and observe effects of rotating a Nicol's prism over the eyepiece on the illumination of the crystals, and they should rotate the light like tourmaline. The alkaloids quinidine, cinchonine and cinchonidine give crystals of similar activity and 0.0005 mgm. of quinine can be detected in 40 c.cm. of water.

4. *Tanret-Mayer Test.* The reagent is prepared by dissolving 1.45 gm. of HgCl_2 in 80 c.cm. of distilled water and 5 gm. of KI in 20 c.cm. of

distilled water and mixing them in a 100 c.cm. measuring flask. The HgCl_2 solution is poured into the KI solution agitating all the time, water is added to make it up to 100 c.cm. This reagent precipitates all alkaloids and gives a good rough test for the presence of quinine in urine. The urine is acidified and boiled to free it from albumin and is filtered. Five c.cm. of this is taken in a test tube and Tanret Mayer Reagent is added. A precipitate shows the presence of the alkaloid. If there is no distinct turbidity the patient has not taken quinine. Mann suggests taking 50 c.cm. of urine and adding 2.5 c.cm. of lead acetate solution (lead acetate 25 gm., glacial acetic acid 2.5 c.cm., water to 100 c.cm.); mix thoroughly and add 2.5 c.cm. of saturated aqueous solution of ammonium sulphate; filter till a clear lead-free filtrate is obtained. Receive a drop of filtrate on a paper moistened with a sulphide to test for lead and also boil to test for albumin. To 10 c.cm. of this add 0.5 c.cm. of Mayer's reagent. An opalescence or turbidity indicates the presence of quinine. Very slight traces of quinine may only show after the mixture has stood for 10 to 15 minutes.

Another simple test for quinine in urine is to take 10 c.cm. of lead-free urine as obtained in the above test and adding to it 6 drops of 1.0 per cent. solution of picric acid. A cloud forms if quinine is present, disappearing on heating and reappearing on cooling. A precipitate due to albumin increases on heating and falls on standing. The test responds to 3 grains of quinine taken an hour before examination.

Quinine mixtures used in dispensaries in this country are not infrequently below strength. Two methods for testing the approximate quantity have been described.

Sinton's method: Prepare Tanret's modification of Mayer's reagent. Heat a portion of the quinine solution to exclude the presence of albumin. If albumin is present it must be removed before testing the solution. Acidify with acetic acid, boil, and filter the solution. Take 4 c.cm. of the quinine solution freed from albumin, place it in a flask, and dilute with distilled water to 250 c.cm. In one of the special spare tubes provided with each set of Brown's opacity tubes for vaccine preparation place one volume of the quinine solution. Add to it one volume of Tanret's reagent and shake well. The solution will become more or less opaque.

Match the opacity with Brown's tubes. This is done by taking the tube under test in turn with each of the standard opacity tubes, and laying the tubes side by side in a good light, upon some clearly printed book. The lighting must be equal in the two cases. The opacity of the two suspensions can then be readily compared by rolling the tubes from side to side, and raising them slightly from the surface of the print. Brown's tubes are numbered from 1 to 10, and Sinton states that these numbers may be taken to represent the number of grains per ounce in the quinine solution under test. A quinine solution

containing 10 grains of quinine to the ounce should show an opacity of 10

As a control to the test, a fresh solution of 10 grains of quinine to the ounce should be made up and tested at the same time. If the solution is weaker than 10 grains to the ounce, solutions of different strengths can be prepared from the control solution by diluting it, and the tests repeated until a match is obtained.

5. Megaw, Ghosh and Chatterjee method:

Requirements:—(1) A supply of long narrow test tubes of equal calibre (5 to 7 mm diameter if possible). Wider tubes may be used but they would necessitate the use of larger amounts of the solutions. Calibrated and graduated tubes such as centrifuge tubes are preferable if available.

(2) **Reagent:—**Twenty gm. of Merck's pure phosphotungstic acid is dissolved in 100 c.cm. of 12.5 per cent. sulphuric acid. The dilute H_2SO_4 is made by mixing 5 c.cm. of B.P. concentrated sulphuric acid of 1.84 specific gravity with 50 c.cm. water, cooling, and making up to 70 c.cm. with more water.

(3) The stock solution which is to be tested. (This should be diluted if it contains more than 20 grains of the alkaloid in each ounce; in this case, the control solution should be diluted in the same proportion).

(4) A freshly prepared solution should be made up in one's presence, using the same amount of quinine or cinchona febrifuge as is supposed to be present in the stock solution, the powders which are in stock in the dispensaries being employed. In cases of doubt as to the purity of the powdered alkaloid in stock, another solution should be made using powders of known purity. This will serve as a control of the quality of the stock powders.

Method —In one tube take 1 c.cm. (or one part) of the stock solution, in another tube take exactly the same amount of the freshly prepared solution (a third tube may be used for the solution made from alkaloids of known purity). Measurement by a pipette is desirable but with reasonable care equal quantities can be measured.

To each of the tubes add 2 c.cm. (or 2 parts) of the reagent and 1 c.cm. (or 1 part) of water. Mix thoroughly by rolling the tubes between the hands for about a minute keeping them in a vertical position. Do not stir or shake the solutions. Allow the precipitates to settle for 2 or 3 hours and compare their heights. Any great variations will indicate the necessity for an accurate quantitative examination of the stock mixture.

If centrifuge tubes and a centrifuge are available the examination can be completed in a few minutes, but the test has been specially worked out so that it can easily be carried out with the simplest possible equipment.

The test solution ready made up can be obtained from any reliable chemist by supplying him with the formula. It keeps indefinitely. It is essential that the tubes employed should be of equal calibre and the quantity of the quinine solution in each tube must be the same. The total volume should be such as to give a 5 per cent. solution of sulphuric acid, at which the reagent acts best. No claim of great accuracy is made for this test, but it will be found useful as a rough check of the strength of dispensary solutions. As already stated, it can also be used to detect any serious deficiencies in the purity of the powders from which the stock mixtures are made. Messrs. Boots Pure Drug Co., Ltd., have prepared a handy 'Quin-Iodide Test Outfit' based on this method.

Hydroquinine. This compound is commonly present in the commercial sulphate of quinine from 1 to 2 per cent. It is best prepared by re-crystallising commercial quinine from hot water and treating the mother liquor with potassium permanganate. It forms two series of salts—the neutral and the acid salts. The dosage is the same as for quinine.

Cinchonidine is an isomeride of cinchonine, and occurs especially in the bark of *C. succirubra*, *C. officinalis*, *C. lucujensis*, and *C. lancifolia*. The sulphate has largely been used to adulterate quinine as it is much cheaper.

Preparation. Cinchonidine is isolated from the liquid strained off from quinine. It is separated as a tartrate, cinchonidine tartrate being only slightly soluble in water.

Properties. Cinchonidine behaves as a diacidic base and yields two series of salts. The neutral sulphate is sparingly soluble but the acid sulphate is easily soluble in water. Neutral and acid hydrochlorides are also soluble.

Tests. Cinchonidine differs from quinine and quinidine in that it does not give the thalleioquin reaction and is not fluorescent in dilute sulphuric acid solutions, and from cinchonine in being more soluble in ether, in the sparing solubility of its tartrate and in being laevorotatory.

Dose. It has largely been employed in the treatment of malaria unknowingly as it is commonly used to adulterate quinine. It is less toxic than quinine and 10 to 15 grains may be given two or three times a day.

Hydrocinchonidine is the hydro-compound of cinchonidine and occurs in most varieties of cinchona bark especially the *C. rosulenta*, and *C. lancifolia*. It may be prepared from commercial cinchonidine sulphate by fractional precipitation. The dose is the same as that of cinchonidine.

Quinidine. This isomeride of quinine is contained in small quantities in most cinchona barks, but especially in *C. pitayensis*, *C. amygdalifolia* and *C. calisaya*.

Preparation. The mother liquor after the separation of quinine sulphate is treated with caustic soda, which precipitates the remaining alkaloids. These are now extracted with ether. The ethereal residue is dissolved in dilute sulphuric acid, neutralised exactly with ammonia, and sodium potassium tartrate is added which precipitates the cinchonidine. The filtrate is now treated with KI solution which precipitates the quinidine as hydriodide. From this it is removed and recrystallised from boiling alcohol.

Properties. Quinidine is alkaline in solution and behaves as diacidic base forming two series of salts. The neutral and acid sulphates are soluble in water. The acid hydrochloride is sparingly soluble. The melting point of the base is 171.5°C and the optical rotation is $+236.7^{\circ}$ in 97 per cent. alcohol.

Tests. It is fluorescent in dilute sulphuric acid and gives the thalleioquin test. It differs from quinine in being dextrorotatory, possessing a sparingly soluble hydriodide (1 in 1250 at 12°C) and a neutral sulphate fairly soluble. The tartrate is soluble and this fact is utilised in the separation of cinchonidine.

Dose. It has a much more powerful action on the heart than quinine, 5 to $7\frac{1}{2}$ grains is the usual dose given two or three times a day orally.

Hydroquinidine is the hydrocompound of quinidine and occurs in commercial quinidine.

Cinchonine occurs constantly in cinchona and cuprea barks, but the amount present is small and shows great variations. One of the best sources is *Cinchona micrantha* bark.

Preparation. After quinine sulphate has been separated, the mother liquor is treated with caustic soda solution, when the remaining alkaloids come down as a precipitate. The precipitate is extracted with ether and the insoluble residue is boiled with successive small quantities of alcohol, and on cooling cinchonine crystallises out. The crude alkaloid is exactly neutralised with dilute sulphuric acid and the sulphate recrystallised from boiling water.

Properties. Cinchonine behaves as a diacidic base and gives two series of neutral and acid salts. The melting point of the base is 264° and the optical rotation $+229^{\circ}$ in dry alcohol.

Tests. Cinchonine differs from quinine and quinidine in that it does not give the thalleioquin reaction and is not fluorescent in dilute sulphuric acid, and from cinchonidine in that it is sparingly soluble in ether and is dextrorotatory.

Dose. It is one of the most toxic of cinchona alkaloids. More than 10 gr. twice a day, is not generally tolerated.

Hydrocinchonine is the hydro-derivative of cinchonine and occurs in most varieties of cinchona bark and is a constant constituent of commercial cinchonine.

B. Amorphous alkaloids.

Quinoidine is the name given to the combined amorphous alkaloids which remain in the mother liquor after the crystalline alkaloids are removed. Acton (1920), Fletcher (1923) and others found them too poisonous to be used in therapeutics, while Waters (1916) and Prain (1924) consider them to be entirely non-toxic and as effective against malaria as quinine. It is held that these substances being amorphous are more readily absorbed and are of greater value than quinine salts. Benign tertian required 9 to 13½ grains of quinoidine to stop fever, while malignant tertian required 10 to 16 gr. and quartan on an average 22 to 24 gr. *Laverain tablets* contain 2 gr. of quinoidine, ¼ gr. of ammonium picrate and 1/100 gr. of arsenious acid; dose 6 to 12 tablets in the day. The preparation is said to be prompt in reducing fever. *Esanofele* is a similar preparation.

Fletcher (1924) reinvestigated the subject and found they had no action whatever against malaria when given in 5 grain doses twice a day. Ten grains twice a day were effective but toxic, the chief symptoms being vomiting and diarrhoea. Both *cinchona febrifuge* and *quinetum* contain large quantities of cinchona alkaloids.

Cupræ cortex or **Cuprea bark** is obtained from *Remijia pedunculata* and other species. It contains quinine and an allied alkaloid, cupreine. A number of derivatives of the aliphatic series have also been prepared. It will therefore be useful to mention some of these preparations in this connection.

Methyl hydrocupreine hydrochloride is also known as hydroquinine hydrochloride. Dose 4 to 12 gr. (0.25 to 0.8 gm.) for adults in malaria. In whooping cough in children it is given in 1 to 5 or 6 gr. intramuscularly, according to age.

Ethyl hydrocupreine or **optochin**, is a white amorphous powder with a bitter taste, almost insoluble in water, soluble in alcohol, ether, chloroform and dilute acids. Dose 3 to 4 gr. (0.2 to 0.25 gm.). It is used in pneumonia. **Ethyl hydrocupreine hydrochloride** is given in the same dose as the base and it is soluble in water.

Iso-amyl hydrocupreine. This derivative according to Dixon (1920) is 10 to 20 times more powerful than quinine in the destruction of protozoa, 0.1 per cent. solution acts as a germicide and as a local anæsthetic.

Iso-octyl hydrocupreine or **vuzin** is said to have a specific action on *C. diphtheria* and enough can be given in medicinal doses to clear this organism from the blood.

CHAPTER XXV

OTHER ANTIMALARIAL REMEDIES

PLASMOQUIN

Owing to the high price of quinine, its bitter taste, and its failure to remove crescents from the blood, attempts have been made from time to time to find stronger and better substitutes for it. These researches led to the synthesis of various antipyretic drugs, such as antipyrin (1884), phenacetin (1886), etc. In 1926, Professor Schulemann and his colleagues chose methylene blue as the starting point for investigation and they prepared a large number of compounds. One of these as tested by Roehl was found to be particularly effective against bird malaria; this was an amino-quinoline in which a basic aliphatic radicle was united to a quinoline nucleus by a connecting link of nitrogen. The structure of this drug has not been wholly disclosed, but according to Horlein (1926), the compound is *n*-diethyl-amino-isopentyl-8-amino-6-methoxy-quinoline, thus differing from quinine principally in the absence of quinuclidine with two intermediate CH_2 radicals. Plasmoquin while not a derivative of quinine is genetically related to that alkaloid. The first announcement concerning it was made in September, 1926. It has also been called 'plasmochin' and later in English-speaking countries it was called plasmoquin or plasmoquine. 'Beprochin' is a substance of a similar nature. Both these substances are very expensive. *Fourneau 664* is another compound allied to plasmoquin. *Dimeplasmin* is a synthetic remedy of the plasmoquin group, prepared by the manufacturers of plasmoquin. A large amount of experimental work was done at first on bird malaria by Roehl (1926). It had been shown that apart from arsenicals, the substances effective against malaria in man are effective against bird malaria also. This process was reversed in the case of this drug and it was found that a drug useful in bird malaria was found to be beneficial in malaria in man. Roehl found that plasmoquin

had a definite destructive action on the plasmodium in the birds and was nearly 60 times stronger and more effective than quinine. One c.cm. of 1 in 50,000 solution of plasmoquin given daily for 6 days delays development of plasmodium in canaries while the same quantity of 1 in 800 solution will be necessary in man. These results were confirmed in bird malaria by Hegner and Manwell (1927). Later, it was found that *Hæmoproteus* may be temporarily removed from the peripheral blood of thrushes; in pigeons plasmoquin removes the gametes of *Hæmoproteus* from the peripheral blood stream, though they return again after a few days. Plasmoquin destroys the gametocytes, but not the schizonts.

Pharmacological action. On non-pathogenic protozoa such as paramœcia, plasmoquin like quinine has a lethal action but in double the concentration of the latter drug. In the dark however plasmoquin is more effective than quinine as light seems to activate the latter drug. When the two drugs are mixed they appear to reinforce each other's action and the toxic action on paramœcia is intensified.

Circulation. Eichholtz (1927) studied the action of this drug on the circulation. In cats, doses of 2.5 to 5 mgm. per kilo. of body weight caused formation of methaemoglobin. In cats, dogs and rabbits, intravenous injections produced cardiac incoordination. In large doses (1 to 3 mgm. per kilo. of the body weight) the drug increases the refractory period of the ventricles and heart-block may be produced. The heart becomes irregular, there may be duplication or suppression of the systole. With higher doses the heart is depressed and the blood pressure falls. Adrenalin brought about normal rhythm in the heart poisoned with plasmoquin and produced the usual rise of blood pressure. Like quinine it does not decrease the number of white blood corpuscles but in a few cases actual increase was noticed in man. Quinine in certain doses is said to prevent the toxic effect produced on the heart and that is the reason why plasmoquin and quinine are combined in the form of plasmoquin compound tablets. This however seems to be doubtful. Leucocytosis sometimes follows the administration of plasmoquin, many young undifferentiated leucocytes being present. It is therefore preferred in malaria complicated with pneumonia.

Uterus. Chopra and his co-workers (1933) have shown that plasmoquin in therapeutic doses has no action on the uterus. In large doses it produces contractions of the isolated uteri of cats and guinea pigs. That plasmoquin prevents the stimulant effect of quinine on the uterine contractions is not borne out by experiments. When proportionately equal doses are employed the action of plasmoquin in the cat and man is similar.

Central nervous system. Plasmoquin is poisonous to the central nervous system.

Excretion. The fate of plasmoquin in the body is not known. That it is partially excreted in the urine there is little doubt. Its presence can be actually detected in the urine. To detect plasmoquin in urine take 200—300 c.cm. of the urine, add 20 c.cm. of 50 per cent. liquor potassae and centrifuge three times, each time with the addition of 30 c.cm. of pure ether. Take out the ethereal solution, and it turbid add a few drops of alcohol, filter and wash twice with 10 c.cm. of water containing two drops of NaOH. Shake well, allow to settle and draw out the aqueous layer. To the ethereal solution add 6 c.cm. of 2 per cent. acetic acid, and shake well, take off the acetic acid solution containing plasmoquin and heat on a water bath for some time to remove the residual ether. Add 3 c.cm. of pure glacial acetic acid and about 0.05 gm. of chloranil (tetrachlor-benzoquinone) and lightly boil the solution. An intensive blue colour reaction develops which shows the presence of plasmoquin.

Toxicity. The lethal dose in rabbits is 3.5 mgm. per kilo. body weight intravenously, 20 mgm. subcutaneously and 225 mgm. by the mouth. In the cat it is more toxic, 5 mgm. intravenously is fatal while the same amount will kill when given subcutaneously and 7.5 mgm. by the mouth. Cats recover more quickly than rabbits after sublethal doses. Death occurs with symptoms of dyspnoea, asphyxia, bradycardia and arrhythmia, with methaemoglobinaemia. It has been shown that plasmoquin forms methaemoglobin with the blood of the sheep, ox, horse, cat, rabbit, dog and man *in vitro*. In man one-third of the oxygen capacity of the blood may be lost, as the result of this conversion. In acute poisoning the symptoms appear in the following order. First there is paralysis of the vasomotor system with fall of blood pressure, slowing and then complete cessation of respiration; the cardiac rhythm remain undisturbed till the end. Lethal and therapeutic doses in man are not widely separated.

Effectiveness Against Malaria

The drug was first tried on man by Sioli (1926) who cured several patients artificially infected with malaria in the course of treatment for general paralysis. Muhlen and Fischer (1927) tried the drug in patients suffering from malaria. In a series of 172 cases he found that 0.08 to 0.1 gm. per day was an effective dose in tertian and quartan malaria. The drug was later tried in most of the malarious countries in Europe, the main results of these observations being that plasmoquin in doses of 0.06 gm. per day given daily for one week, and for 3 days in the week for five weeks was effective in curing malaria. This was

the method recommended by the manufacturers. Sinton (1928) gave the drug daily for 28 consecutive days and found this method more effective though more toxic. The conclusions arrived at are that the destructive action of plasmoquin is restricted to infections by *P. vivax* (benign tertian) in all phases, and that while it has no action on the schizonts of *P. falciparum* (malignant tertian) it has a definite action on the crescentic gametocytes of this organism.

Action in benign tertian and quartan malaria. Both benign tertian and quartan parasites disappear from the blood more rapidly than the sub-tertian, and cure is said to be more readily effected in these infections than with quinine. After doses of 0.01 gm., 4 or 5 times a day or 0.06 gm. daily, the fever usually disappears from the first to the third day of treatment. The parasites may disappear as early as on the 2nd day or as late as on the 7th day of treatment. Relapses do not occur so frequently as with quinine. Sinton (1928), who watched his cases for long periods, found that 30 per cent. of patients suffering from benign tertian infections relapsed after intermittent treatment with plasmoquin and 23 per cent. relapsed after ordinary treatment with quinine. Immediate results however obtained in acute attacks after treatment with this drug were no better than those obtained with cinchona alkaloids. In quartan fever similar results were obtained but the parasites remained somewhat longer in the peripheral blood. Although the number of cases was small, no relapses were reported in quartan fever. Plasmoquin and quinine together, are believed by many authorities to be more effective in destroying the sexual forms of benign tertian and quartan parasites, than quinine alone.

Action in subtertian malaria. As regards subtertian infections, plasmoquin has no action at all upon the schizogony cycle, and the parasites multiply unchecked. On the other hand it has the unique and remarkable property of completely destroying the gametocytes or 'crescents',—a property which is not possessed by either quinine or atabrin. This effect on the crescents can be studied microscopically; on the first day after plasmoquin administration the crescents are seen to be degenerat-

ing and stain badly ; on the second day they are so degenerated as to be hardly recognisable ; on the third day none are found. Hence in subtertian malaria the administration of plasmoquin has to be supplemented, either with quinine or atebirin. If a patient suffering from subtertian malaria be treated only with quinine or atebirin and is clinically cured, to turn him out of hospital at this stage with his blood loaded with crescents, fully infective to mosquitoes, is a crime against public health, since he may infect hundreds of mosquitoes in his home with malaria. In all cases of subtertian malaria, after the patient has been cured with quinine or atebirin, a short course of plasmoquin—0.01 gm. twice daily for three days—should be given. This will ensure that the patient is not a danger to the countryside when he returns to his home.

Effects on the gametocytes. Plasmoquin has a definite destructive action upon the gametocytes and removes the crescents from the peripheral blood in a very short time. None of the cinchona alkaloids have any effect on the crescents, nor do the arsenicals or the aniline dyes affect them adversely. Even small doses (0.02 to 0.04 gm.) of the drug daily for three days are said to render the peripheral blood non-infective to anopheline mosquitoes; a single dose may render crescent-containing blood non-infective for three days. These facts are of great importance from the point of view of the transmission of malaria from one person to another.

Fletcher (1927) said that plasmoquin has the property of destroying the gametocytes of malignant tertian infection and this unique attribute holds out a hope for eradicating malaria by mass treatment. Manson-Bahr (1928) states that within 36 hours of the administration of 0.08 gm. plasmoquin and 1 gm. quinine, crescents are deformed and in 60 hours they are completely disintegrated. The average time and quantity required for disappearance of the crescents from the blood were 4 days and 0.3 gm. respectively. Mollow (1928) described the direct toxic effect of the drug on the crescents and the changes which take place in these bodies. Definite signs of degeneration were noted in crescents within 36 hours of the commencement of plasmoquin medication, and 24 hours later the crescents were

entirely disintegrated. According to Fischer and Weise (1927) the daily dose of the drug, to remove the crescents from the blood, is 0.02 to 0.03 gm. ($\frac{1}{3}$ to $\frac{1}{2}$ gr.).

Practical trials of antigametocyte action of plasmoquin have been made by Clemesha (1933). Although the trials were on a small scale, the results show that it is possible to control the spread of malaria by careful antigametocyte work. Two doses of quino-plasmine a week usually effect a great reduction of parasites (trophozoites or schizonts) in the peripheral circulation. Malignant tertian and benign tertian gametocytes are never found if the dose is taken regularly. Quartan parasites are less acted upon by plasmoquin than other two varieties. Two doses of quino-plasmine a week cause the attack, even of malignant tertian, to be mild in character. The objection to this procedure is the trouble and expense involved; but the cost is much less than that occasioned by a severe outbreak of malaria.

Plasmoquin compound. The insufficient action of plasmoquin on the ring forms and schizonts of subtertian malaria led to the use of a combination of plasmoquin and quinine sulphate. This is given in tablet form, each tablet containing 0.005 gm. of plasmoquin and 0.0625 gm. of quinine sulphate, but the quantities of both drugs are very small and tablets containing double the strength, *i.e.*, 0.01 gm. and 0.125 gm. respectively are more convenient. In this proportion the toxic effects of both the drugs are minimised. It is desirable that the dose of 0.06 gm. of plasmoquin per day should not be exceeded, as otherwise toxic symptoms are produced. A much smaller amount than this may effect a cure and the presence of small quantities of quinine, which otherwise would not be effective, gives better results when combined with plasmoquin.

In subtertian malaria treated with plasmoquin compound, the fever usually disappears after 2 to 3 days, and the parasites between the 2nd and the 7th day. Relapses do occur but they are not so frequent as with quinine alone. This is not borne out by Sinton's observations and in a large series of 554 cases treated by Olivier and Hulshoff in Java no relapses occurred after treatment with plasmoquin compound.

Muhlen (1927) and Hasselmann (1929) advised 6 tablets of plasmoquin compound daily in divided doses, each tablet containing 0.01 gm. plasmoquin and 0.125 gm. quinine.

Macphail (1930) in the Fruit Company hospital in Guatemala gave a routine treatment of three tablets of plasmoquin compound daily for six days, together with 15 grains of quinine twice daily. No toxic symptoms resulted in 20,000 cases treated.

Quinoplasmine. This is the commercial name for tablets of plasmoquin 0.01 gm. and quinine 0.3 gm. Four tablets are given daily for 4 to 21 days. With this treatment 100 per cent. of definite cures in quartan malaria and 4 per cent. relapses in benign tertian malaria have been obtained.

Other effects. With the subsidence of fever the blood condition is improved, the anaemia disappears and the hæmoglobin content is increased. A marked decrease in the size of the spleen has been noted by a number of other observers. Sinton on the other hand found that the reduction was no more marked than with ordinary quinine treatment, but this was probably due to the fact that most of his cases were those of chronic relapsing malaria.

In cases of malaria complicated with ear diseases (*e.g.*, internal and middle ear disease, deafness) and also in menorrhagia, where quinine is not indicated, plasmoquin is specially suitable. The drug is well borne in pregnancy and is not affected by the presence of intercurrent diseases such as tuberculosis of the lungs, nephritis, valvular disease of the heart, pneumonia, jaundice, typhoid, etc. Children and even infants bear plasmoquin very well and further it has the advantage of being tasteless. It has also been used in the treatment of blackwater fever in place of quinine, but in view of the dangerous and even lethal effects that are sometimes noticed with the drug, plasmoquin should not be used in such cases; atabrin is better as a substitute for quinine.

Dosage. The maximum dosage without producing toxic effects is 0.03 gm. per day. According to Muhlen the dosage for quartan and tertian malaria is 6 plasmoquin compound tablets daily each containing 0.01 gm. of plasmoquin and 0.125 gm. of quinine divided into 2 or 3 doses. This means 0.06 gm. of plasmoquin and 0.75 gm. of quinine per day; 0.02 gm. may be given 3 times a day for a week. The fever disappears in 1 to 2 days and the parasites in 5 or 6 days. The amount of quinine to be given daily in combination with

plasmoquin depends on clinical symptoms. In chronic cases with acute symptoms 1.0 gm. may suffice. In acute cases it may be necessary to give larger doses. In ambulatory cases not under daily supervision not more than 0.04 gm. of plasmoquin should be given daily for periods not exceeding six days. Manifold (1931) adopted a standard treatment of one tablet of plasmoquin 0.02 gm. and 10 grains of quinine morning and evening. In malignant tertian cases the drugs were continued for 21 days. It has recently been claimed that plasmoquin in 0.02 gm. doses effectively prevents mosquito-borne malaria infection; quinine lacks this remarkable property.

The patient as a rule does not develop tolerance to this drug. Interrupted treatment as a rule is more satisfactory, the drug being given twice a week for 4 to 6 weeks.

Children tolerate plasmoquin very well and it has the advantage of being tasteless. Infants 6 months old can be given 0.005 gm. twice daily without ill effects.

Toxic effects. Like most of the highly efficacious synthetic remedies plasmoquin is a toxic drug. The appearance of untoward effects depends not only on the dosage given but on the temperament and susceptibility of the patient. Nervous patients are particularly liable to suffer. Cyanosis and epigastric pains were observed very early after trials in man, and they are universally present though they vary a great deal in their intensity in different individuals. Slight jaundice, cyanosis and abdominal pains are by no means rare. The appearance of cyanosis ought to serve as a warning to reduce the dose or to stop the drug. Cyanosis has appeared after 0.08 gm. In mild cases there may only be cyanosis of the fingers, toes and lips but the face and the whole body may be involved. According to some it rapidly disappears on subsequent treatment with quinine, plasmoquin and quinine being mutually antagonistic in this respect. Abdominal pains and gastric disturbances are common when the drug is given on an empty stomach in large doses. Some believe they are due to rapid decrease in the size of the spleen. Muhlens and others state that these pains do not appear if the drug is given after meals. Sliwensky (1927) gave a whole day's dose amounting to 0.06

to 0.08 gm. all at once after the morning meal and never observed any gastric disturbances. Others have reported sudden attacks of pain which became very alarming and in many cases a course of treatment cannot be finished without toxic symptoms.

Intoxication symptoms as a rule have not been recorded unless the dose reaches 0.18 gm. The face is livid grey, but there is no dyspnoea nor undue distress. The patient complains of headache, dizziness, curious clammy sweats, abdominal pains, vomiting and a sensation of bruising over the lower ribs. The pain may be specially marked in the region of the liver, and central necrosis of liver lobules has been observed. In some cases the symptoms resemble an attack of cholera,—subnormal temperature, vomiting, diarrhoea and cyanosis being present. Cyanosis may be associated with haemoglobiuria, involvement of the liver and intestinal symptoms. The blood turns chocolate coloured and methaemoglobinaemia and methaemoglobinuria occur. Urobilinogen appears in the urine simultaneously with the administration of the drug and persists for several days. The patient turns drowsy and becomes comatose. Pallor with marked drop of erythrocytes and haemoglobin count, exhaustion, and yellowness of the skin, are some of the symptoms. Haemoglobin falls to 30 per cent. the leucocyte count rises to 24,000 per c.mm., and the oxygen capacity of the blood is decreased. In one case symptoms appeared after 0.4 gm. of plasmoquin in daily doses of 0.12 gm. Methaemoglobin appeared in the urine 24 hours after cyanosis and was accompanied by albumin and casts. The picture resembled that of mild blackwater fever. Jaundice may occur. Cyanosis may last for 24 hours after the drug is stopped but rarely may last as long as seven days. The serum becomes brownish with a strong direct bilirubin reaction and with urobilin strongly positive. There is a good deal of destruction of red corpuscles the number falling to half the normal amount. Many explanations have been given for the occurrence of cyanosis. It has been said to be due to disturbance of the heart rhythm, but most authorities believe it to be due to the formation of

methaemoglobin, which has been detected in the urine and in the serum.

There is no direct connection between the amount of the drug given and the quantitative degree of change in the blood, although the most violent symptoms are only seen after large doses. The number of erythrocytes present in the blood appears to have a great influence on the toxic symptoms. The greater the anaemia, the quicker and more violently methaemoglobin is formed, and the deeper is the cyanosis. It follows therefore that patients suffering from secondary anaemia should be given only small doses of plasmoquin. The temperature of the individual is also a determining factor, the higher the temperature the more quickly is methaemoglobin formed. In certain patients cyanosis occurs even with small doses of the drug. The quinoline chain apparently is not responsible for the formation of methaemoglobin, but probably the alkamino group is really responsible and this occurs in such methaemoglobin-forming drugs as acetanilide and phenacetin. Cyanosis generally appears on the 5th or 6th day of the treatment.

A direct haemolytic effect on the part of this drug is disclaimed and it is believed that it acts on the reticulo-endothelial cells (Kupfer's star-cells) of the liver, whereby its detoxicating properties are decreased.

On account of the frequency of toxic symptoms, which are sometimes of an alarming nature, plasmoquin should only be used under hospital conditions. The drug is not as suitable for mass treatment as is quinine.

Prevention and treatment of toxic effects. The poisoning can be prevented by careful dosage, taking into consideration the body weight and general condition of the patient. A few drachms of glucose given daily, either in powder or liquid form, may prevent the onset of toxic symptoms. The drug should be given an hour and a half after a light meal. The bowels should be kept open. When symptoms have supervened the drug should be stopped and the patient strictly confined to bed and given copious alkaline drinks. Stimulants and mild non-irritating diuretics are indicated. In

severe cases of methaemoglobinaemia and methaemoglobinuria the patient may be benefited by transfusion of blood.

Prophylactic value. Owing to the action of plasmoquin on the gametocytes, the question of its utility in malaria epidemics is worth considering. Experiments carried out in Java showed that plasmoquin had a well marked prophylactic value, especially in benign tertian malaria. In Bulgaria trials on a small scale showed that administration of plasmoquin compound to gametocyte-carriers in doses of 0.07 to 0.08 gm. daily for six days kept them parasite-free for 4 months. It is suggested that if this procedure can be carried out in malaria-stricken areas 2 or 3 weeks before the anopheles period, the number of fresh infections could be considerably reduced. Clemesha (1933) obtained good results with two doses of quinoplasmine a week.

Plasmoquin in doses of 0.08 gm. on the day before infection, the day of infection, and the day after, and subsequently in doses of 0.06 gm. for the following five days is said to be a true causal prophylactic. Such doses, however, are liable to produce toxic effects. A daily dose of 0.04 gm. on the day before infection, the day of infection and for eight days after infection will always prevent the onset of a malarial attack within the usual incubation period, but will not prevent the person having a latent infection which may become manifest at a later period, usually six to ten months after infection. With smaller doses failures are more frequent. Some workers have found that daily doses of 0.02 gm. of plasmoquin prevented to a great extent fresh infection, but not when doses were given only three times weekly. Such doses even when given daily are not sufficient to kill all sporozoites injected, though they keep the malarial manifestations below the febrile threshold while the drug is being administered. This is evident from the fact that many persons develop clinical malaria, shortly after the cessation of the drug. It will be seen, therefore, that plasmoquin is not adoptable for prophylactic purposes in malaria.

Plasmoquin in pregnancy. In therapeutic doses plasmoquin has no effect on the uterine contractions and it is considered to be a safer drug than quinine in malaria in pregnancy.

Mode of action of plasmoquin. The exact manner in which plasmoquin produces its destructive action on the malarial parasites is not understood. It has been suggested that the action of plasmoquin in malaria may be at least partly due to its

capacity of converting haemoglobin into methaemoglobin. This would lead to the lysis of the red blood cell and consequent destruction of the parasite.

Plasmoquin in blackwater fever. Plasmoquin has been employed in cases of quinine idiosyncrasy and blackwater fever and it appears to be well borne. The dosage was very slowly increased, *i.e.*, beginning with 0.01 gm. per day and increasing gradually to 0.06. It causes disappearance of malarial parasites from the blood and haemoglobinuria disappears in 24 hours. Administration of quinine may again produce haemoglobin in the urine in these cases. Cases of malaria with idiosyncrasy to quinine have been successfully treated with plasmoquin.

Conclusions. Plasmoquin is a toxic drug, and the hope that it will replace the cinchona alkaloids in the treatment of malarial fever has not been fulfilled. On account of its toxic effects it has to be given under strict medical supervision. Its employment is indicated where there is idiosyncrasy to quinine, and in pregnancy where there is risk of abortion from the use of quinine. A safe dose is 0.06 gm. per day as it is therapeutically effective and less likely to produce toxic effects. Children tolerate it well and in malaria of infants it is very useful. A combination of plasmoquin with quinine, is equal if not superior to quinine alone. Its action in rendering gametocytes non-infective to mosquitoes is of very great importance, and with plasmoquin compound there is possibility of sterilising the carriers. Plasmoquin by itself should never be used in the treatment of malarial fevers. For the treatment of benign tertian the combination with quinine (plasmoquin-compound) is most suitable, it having been found that a small dose is quite sufficient if supplemented with quinine. In malignant tertian it is not curative, but its action on the gametocytes has led to its employment as an antigametocyte, a measure which has been shown to be a practical form of malaria control.

Preparations.

Plasmoquin is issued in tablets in three varieties:—

Plasmoquin simplex 0.01 and 0.02 gm. Dose 1 to 3 tablets daily.

Plasmoquin compound containing plasmoquin 0.01 gm. and quinine 0.125 gm.

Quinoplasmine or **quino-plasmoquin** containing plasmoquin 0.01 gm. and quinine 0.3 gm.

ATEBRIN

Six years ago the introduction of plasmoquin marked the inauguration of the use of synthetic compounds in the treatment of malaria. Plasmoquin, however, has not entirely replaced quinine. Its action on the parasites is different; plasmoquin destroys the sexual forms of *P. falciparum*, thereby interrupting the transmission cycle, but it has no action on the asexual forms. This limitation of plasmoquin indicated that further research was necessary, and as a result the makers of plasmoquin recently announced the introduction of a new compound called *Atebrin*. The product, first called 'erion' or 'plasmoquin E', is the dihydrochloride of an alkylamino-acridine derivative; it is a yellow powder having a bitter taste, soluble in water 1 : 14 forming a neutral fluorescent solution. Both drugs have been evolved by using the structural formula of methylene blue as a starting point.

Pharmacology. Administered by the mouth, atebrin is quickly absorbed from the small intestine and passes into the blood stream whence it is slowly excreted unchanged by the kidneys and the biliary tract. It is fairly well tolerated but when large doses are administered in animals, diarrhoea and reflex salivation occur. Frequent vomiting is also noticed. The diarrhoea however usually subsides within 24 hours. If the drug is injected intravenously into rabbits under anaesthesia, a fall of blood pressure is obtained within 1—2 minutes. This fall is not due to any direct action on the cardiac musculature, but is probably due to a transient dilatation of the capillaries in the splanchnic and peripheral areas. The plain muscles of the small and large intestines and the uterus are not affected in any way after intravenous injections in anaesthetised animals. A slight reduction of temperature ranging up to 1° C. has however been obtained in rabbits with induced fever. This reduction in temperature lasts for about 12 hours.

Fate in the body and excretion. Atebrin is eliminated slowly and may be found in the urine many days after completion of a course. The urine should be examined daily during treatment, as its absence indi-

cates possible accumulation in the system which may give rise to a yellow colouration. The drug is mostly excreted by the kidneys and its presence can be roughly detected in the urine by production of the characteristic yellow colour on addition of an acid. The test suggested by the makers is to extract the alkalinised urine with ether, and dissolve the residue resulting from the evaporation of ether extract in strong sulphuric acid, when a yellow colour appears. This latter test is more accurate, and the author actually uses a modification of it. The urine is first treated with lead acetate to remove all other matter and the lead is removed from the filtrate by the addition of ammonium sulphate. The filtrate is then extracted with ether and tested with acid in the ordinary way. The drug appears in the urine on the second day after administration and can be detected up to 15 or 20 days or even longer. The excretion is not regular and may stop for a day or two and then reappear. The author's observations on Indian patients confirm the view that there is some tendency towards accumulation of the drug in the body. Atebrin undoubtedly persists in the body for a much longer period than quinine or plasmoquin. If excretion is hindered there is a tendency for the appearance of the dye in the skin which assumes a yellowish tinge.

Toxicity. Cats tolerate oral doses of 0.05 gm. per kilo. body weight without any reaction. After administering 0.07 gm. the animals show symptoms of gastro-intestinal irritation. On an average 0.1 gm. per kilo. by the mouth is the minimum lethal dose, the animals dying with symptoms of collapse. If large doses are administered, fatty degeneration of the liver and kidneys occurs. Rabbits tolerate the same dose without any demonstrable injury whatever. Blood changes, especially formation of methaemoglobin, have never been observed. A dose of 0.1 gm. per kilo. injected subcutaneously causes death which is apparently due to anæmic symptoms.

Chemotherapeutic studies. The therapeutic efficacy of the drug was evaluated in bird malaria by Roehl. He worked out a method of using canaries for experiments on lines closely approaching the conditions of practical therapy so that it was possible to try out and assess in the laboratory many groups of drugs. Here it was shown that in bird malaria, the therapeutic index of atebrin was 1:30. Plasmoquin has the same therapeutic index whereas quinine has an index of only 1:4. Atebrin therefore is four times as effective as quinine. Chopra and Das Gupta (1933) carried out elaborate studies on the action of atebrin on plasmodium infections in monkeys and have come to the following conclusions.

Destructive action on the plasmodium. The destructive action of atebrin on this plasmodium appears to be exceptionally powerful. Usually two doses of 0.025 gm. each given either intramuscularly or intravenously are sufficient to control a very heavy infec-

tion which may amount to a million parasites per c.mm. The drug equally effects both the schizogony and the gametogony of this plasmodium and all phases of the parasite disappear rapidly from the peripheral circulation under its action. Even after a single dose, signs of degeneration are seen in the parasites and their numbers rapidly decrease. After two or three doses they disappear from the peripheral blood altogether.

Owing to its slow excretion atebirin, when given intravenously, appears to exert a more prolonged action than quinine on *P. knowlesi*. Our observations show that intravenous injections of quinine are not effective against a heavy infection with this plasmodium in *M. rhesus* unless they are repeated at short intervals, say of three or four hours, but one injection of atebirin suffices. It would appear that the growth of the parasites is not checked by quinine, probably because of its rapid excretion after intravenous injection.

Relapses. Atebrin has earned a great reputation as a powerful remedy in preventing relapses in all species of human malaria. Green (1932) treated 15 cases with 0.1 gm. of atebirin thrice daily for five days with no relapses, while there were 13 relapses among 24 controls treated with quinine. James and his colleagues (1932) treated 15 experimentally infected cases with similar doses and only one relapsed, four of them were chronic cases and had had several relapses prior to treatment with atebirin. Five cases infected at Horton with the 'Rome' strain of *P. falciparum* had no relapse after a course of atebirin, but two controls treated with quinine relapsed. Similar results have been recorded by Sioli, Hooper, De Uells, Jains and many others. In view of this evidence, the drug would appear to be more effective than quinine in curing malaria and preventing relapses, but so far as relapses are concerned this is not our experience with the Indian strains of malaria.

Whatever may be the case with human malaria, in monkey malaria relapses undoubtedly occur. In *M. rhesus* infected with *P. knowlesi* even after 5 days intensive treatment with large doses of the drug, the parasites invariably reappeared in 10 to 15 days and multiplied with the same rapidity as in the primary attack, causing death of the animal if prompt treatment is not given. The recrudescence can however be checked much more easily than the original attack. One dose as a rule suffices to control the multiplication of the parasites though a low grade of infection persists for a long period. After such a dose the parasites appear to lose their virulence and either a scanty infection may persist or the parasites may disappear from the peripheral circulation for long periods without further treatment. Whether in course of time they will regain their virulence is now being studied.

Effectiveness against malaria. The, antimalarial efficiency of the drug was first tested by Prof. Sioli in paralytics artificially infected with benign tertian malaria. He administered the preparation to patients on 3 consecutive days and found that 0.1 gm. three times a day can effectively control the symptoms and cause a disappearance of the parasites. The drug has now been tried in various countries, including the tropics, subtropics and temperate zones.

The toxicity of atebtrin is low, with a wide margin of safety between the effective therapeutic dose and the toxic dose. The new product has been investigated very thoroughly. Unlike plasmoquin, it acts on the asexual forms of the parasites, in which respect it resembles quinine, whereas its therapeutic activity is said by some authorities to be even greater than that of that alkaloid. As atebtrin is more effective than plasmoquin in destroying the ring forms, the formation of crescents may be combated by a combination of the two drugs—0.1 gm. of atebtrin and 0.01 gm. of plasmoquin. Such a combination has been tried but in some cases toxic and even fatal results have been observed. The chief symptoms observed in mild cases are cyanosis and palpitations, but in some cases they resemble severe plasmoquin poisoning. It appears that combination of these two drugs increases their toxicity.

Clinical experiences with atebtrin in the Federated Malay States are also very encouraging. Green, working at the Institute of Medical Research, Kuala Lumpur, tried atebtrin in 50 cases of malaria. He found that in atebtrin-treated cases, the asexual parasites disappeared from the blood within seven days but quartan gametocytes tended to persist after the seventh day. In subtertian cases the gametocytes seemed unaffected by the drug. The conclusion drawn by this worker is that this new drug is definitely more effective than quinine in preventing relapses, when used for short courses of treatment.

Chopra and his co-workers (1933) carefully tested this drug on the Indian strains of malaria and have come to the following conclusions:—

(1) Atebrin is an effective drug in the treatment of Indian strains of malaria. Its destructive action on the asexual forms

of benign tertian, malignant tertian, and quartan types of malaria is about equal, the schizonts disappearing from the peripheral circulation after 0.6 to 0.9 gm. of the drug, *i.e.*, the administration of 3 tablets of 0.1 gm. for 2 or 3 days.

(2) The sexual forms or gametocytes are more slowly acted upon than the asexual forms. The gametocytes of the benign tertian and quartan types are readily destroyed and degenerative changes can be observed in them shortly after the administration of the drug is started. The gametocytes of the malignant tertian type, *i.e.*, crescents, are not affected at all.

(3) The drug is effective in doses of 0.1 gm. three times a day, the course lasting for five days, making a total of 1.5 gm. of the drug for the cure. In the majority of patients such a course is effective, but in a few of the persistent ones it may have to be repeated after a few days interval. The drug can also be effectively given intravenously in doses of 0.1 gm. dissolved in 1 to 2 cubic centimetres of distilled water when the number of parasites in the peripheral blood is large.

(4) In chronic types of malaria the drug is effective and produces a rapid reduction in the size of the spleen.

(5) Atebrin is reported to prevent relapses, but the evidence at our disposal shows that this is not the case with Indian strains of malaria. Its prophylactic value is very similar to that of the cinchona alkaloids.

(6) The blood pressure is lowered in some patients during the administration of the drug, but in the majority it has no effect. The pulse rate and respiration are not markedly affected. It has been used in patients suffering from endocarditis and myocarditis without ill-effects.

(7) The action of atebrin closely resembles that of the cinchona alkaloids and the introduction of this drug is a distinct advance in the treatment of malarial fevers in India. The price at present is too high for its use by the people in general.

Relapses. It has been urged that the most valuable property of atebrin is its power to prevent relapses and many workers have borne testimony to this effect. But in the author's experience quite a number of patients, at least five out of a series of 39, apparently relapsed. It must be pointed out how-

ever that in a malaria endemic area such as Calcutta, it is very difficult to be certain whether these were fresh infections or relapses. Two patients relapsed while they were actually under observation in the hospital after the course, and parasites of the same species were found in the peripheral blood. (A number of relapses were also reported in the patients treated outside the hospital). Even though these may not be real relapses but fresh infections, it may be noted that infection took place before the atebtrin had been fully excreted from the body of the individual. Although in an endemic area like this, it is difficult to prove in the human patients that relapses actually did occur after a course of atebtrin, there is ample evidence in experimental malaria in monkeys (*M. rhesus*) that the drug does not eradicate infection from the body and that relapses are common. In quite a number of these animals after a course of the drug and disappearance of symptoms and parasites from the peripheral circulation, the parasites reappeared usually within two weeks and the animal showed symptoms of the disease.

Prophylactic uses. Atebtrin is claimed to have prophylactic properties and has been used by some workers for this purpose with good results. It is said to have been continued for months in doses of 0.1 gm. daily without producing any untoward effects. It has also been combined with plasmoquin for this purpose, 0.1 gm. of atebtrin and plasmoquin 0.01 gm. being given together daily. The prophylactic value of atebtrin is still under investigation, but so far as we can see it has no more true prophylactic action than the cinchona alkaloids.

The results of experimental trials with atebtrin are precisely the same as those with plasmoquin. Atebtrin in the usual curative doses (0.3 gm. daily for 5 to 8 days) controls the infection to the extent of making it latent for a long period. As these doses of atebtrin are much smaller than those liable to cause toxic symptoms, it is to be preferred to plasmoquin, where the prophylactic dose is the maximum that can be tolerated. A daily dose of 0.1 gm. of atebtrin has proved more effective in keeping infected persons free from fever, than a daily dose of 0.3 gm. (5 gr.) of quinine. The continued use

over a long period does not produce any untoward effects except that there may be a yellow coloration of the skin.

Blackwater fever. Atebrin can be given to patients suffering from blackwater fever without ill-effects. It can also be given to patients who are sensitive to quinine and in whom administration of quinine produces hæmoglobinuria.

Untoward and toxic effects. Atebrin unlike plasmoquin is not a very toxic drug. Double the usual dose of 0.3 gm. per day (*i.e.*, 0.6 gm. in 24 hours) can be tolerated, but larger doses may produce gastro-intestinal irritation. In spite of the tendency referred to above of accumulation of the drug in the system, the author gave two five day courses of the drug with a few days interval between without producing any toxic effects, and with therapeutic benefit. Some patients complained of slight pain or a sensation of uneasiness in the epigastric region soon after taking the drug. This generally started on the second or third day and persisted as long as the drug was being administered. The pain was never so severe as that produced by plasmoquin. In none of our series did we get the severe abdominal pains described by Green (1932). A number of our patients complained of headache and loss of appetite while the drug was being given, but this also passed off when atebrin was stopped. In some patients a profound feeling of general depression started on the third day of treatment and persisted for several days after the drug was stopped. The patient felt as if he had 'no life in him' and had no desire to make physical exertion and wished to remain lying down. In some of the patients diarrhoea was produced on the second and third days of treatment and persisted while the drug was being given. The diarrhoea was of a mild type and no particular treatment was necessary. It stopped with the cessation of the drug. In a few patients, especially those who were obese, palpitation occurred which was quite distressing, but it stopped when the drug was discontinued and in one patient cardiazol had to be administered. In one case mental disturbances are reported to have occurred. A yellow staining of the skin and conjunctiva occurred in several of our patients, but the colouration as a rule was very slight and in none of the patients did it amount

to a jaundice-like appearance. It is not true jaundice. There is no slowing of the pulse or bile pigment in the urine. It represents excretion of the drug by the skin and is merely a yellow discolouration of which the patient is often unaware.

Relative value of atebryn and quinine. Quinine, probably the most useful of the cinchona alkaloids, does not produce the same effect on all species of malarial parasites; it is most potent on the parasites of benign tertian malaria, less active on those of quartan and least of all on those of subtertian malaria. It produces rapid alleviation of the clinical symptoms, but in a number of cases it does not destroy all the parasites, even after a prolonged course it is not toxic in the doses in which it is usually given, but it is not pleasant to take and in many individuals it gives rise to unpleasant symptoms.

Atebrin on the other hand is not unpleasant to take and does not usually give rise to toxic symptoms; where comparatively large doses are used and excretion of the drug is delayed, a yellowish discoloration of the skin appears, but this is of the nature of carotene pigmentation and disappears within 8 to 15 days. Atebrin compares favourably with quinine in ridding the blood of malarial parasites and in relieving symptoms. Atebrin, like quinine, destroys the gametocytes of *P. vivax*, but neither of these two drugs has any action on the gametocytes of *P. falciparum*. Its use, however, over a period of seven days or less destroys the gametocytes of *P. vivax* with sufficient rapidity to prevent mosquitoes becoming infected from benign tertian cases within three or four days of commencing treatment. Among gametocyte carriers of *P. falciparum* neither atebryn nor quinine may be regarded as an efficient drug in preventing the infection of mosquitoes which have access to such patients under treatment.

TEBETREN AND MALARCAN

Hydroquinine or methylhydrocupreine, $C_{20}H_{26}N_2O_2$, is obtained by the hydrogenation of quinine, $C_{20}H_{24}N_2O_2$. A combination of this with an acridine dye and a bile salt has been introduced under the name of Tebetren, which is described as methyl-hydrocupreine-methyl-acridine-dehydrocholate.

The bile salt is said to render the compound less toxic. Malarcan is a preparation of similar nature prepared by an Austrian firm. The drug is available for oral administration in tablet forms of 3 grains each and in ampoules of 2.1 c.cm. and 1.1 c.cm. for parenteral administration.

Stoute (1930) reports a trial of tebetren in about 100 cases, adults and children. The course for adults was two tablets (6 grains), and for children quarter to one tablet according to age, every four hours for thirty doses; four courses were given with a rest of three to five days between courses. Certain by-effects were noticed, such as a feeling of fullness in the head, deafness, and ringing in the ears but these were restricted to the first course. In benign tertian and subtertian the parasites disappeared in about half the time that they do with quinine. Cases resistant to quinine reacted well to tebetren. Cured patients, when safeguarded from re-infection, did not relapse during eighteen month's observation. Subcutaneous injections caused sloughing but intramuscular injections produced no reaction. Barrowman (1933) in the Malaya States found that tebetren is paracitidal to both sexual and asexual forms of all types of malaria. While this may be true of benign tertian and quartan types, the sexual forms of malignant tertian type of Indian strains of malaria are not destroyed by this drug.

Chopra and his co-workers tested malarcan in a series of cases. The drug controlled the clinical symptoms of malaria in much the same way as quinine but parasites took longer to disappear and relapses were more common. It has no effect on the sexual forms of malignant tertian parasites.

Quinoline compounds. Research is still proceeding with a view to the discovery of new antimalarials among the quinoline derivatives. Slater (1930) reports further on quinoline compounds containing arsenic and has prepared several derivatives of quinoline-arsenic acids, which are being tested by the Joint Committee on Chemotherapy formed by the Medical Research Council and the Department of Scientific and Industrial Research in respect of their action on malarial parasites. A number of these compounds has been prepared in India and they are being tested by the author.

OTHER DRUGS USED IN MALARIA

Certain drugs are believed to have some influence in causing the parasites to disappear from the peripheral blood or perhaps in assisting the patient to resist the invasion of the parasites. These drugs can be divided into two groups: (1) those which are given in combination with quinine and (2) those which are given by themselves especially where quinine is not tolerated.

1. Drugs used against malaria in combination with quinine.

(i) Preparations of Arsenic, Antimony, Iron, and Mercury.

Various preparations of arsenic are frequently used in the treatment of malaria. Of the various *inorganic preparations*, liquor arsenicalis (Fowler's solution) and a combination of arsenic, quinine and iron, either in the form of a pill or a mixture have been prescribed. *Mistura arseni quininae et ferri* (Baccelli's mixture) is one of these preparations and it is given in doses of $\frac{1}{4}$ to 1 oz. (15 to 30 c.cm.). Arsenic in inorganic form has been shown to have no action whatever on the malarial parasites.

Organic preparations of arsenic are said to have a marked effect on some of the pathogenic protozoa and are believed by some to have a destructive effect on the malarial parasites. *Neo-arsphenamine* is said to abort the symptoms in practically every attack of malarial fever and thus save the patients from getting attacks of fever which are very debilitating. The convalescence is shortened and the chances of recovery are enhanced. They also have an excellent tonic value and the patients recover quickly and return to work. *Sulph-arsphenamine* in doses of 0.3 to 0.5 gm. subcutaneously or intramuscularly is also effective. Some clinicians combine intravenous injections of arsenicals with quinine as a routine treatment of malaria.

Sodium cacodylas even in doses of 10 grains intravenously had no effect either on the parasites or on the temperature independently of quinine. *Arrhenal* or *new cacodyle* in doses of 8 grains by the mouth proved ineffective. *Soamin* and *arseno-benzol compounds*, *stovarsol* and *treparsol* have been frequently tried either alone or in combination with quinine. The hope that they would be a substitute for quinine has not been fulfilled although some consider that they are effective against benign tertian (*P. vivax*) affections in the acute stage. One gm. of the sodium salt of stovarsol in 10 c.cm. of distilled water given intravenously cleared the blood of *P. vivax* in seven artificially infected and two naturally infected cases and prevented relapses for two months. The drug acted better on old pigmented parasites, the older schizonts and the gametocytes. Sinton (1927) treated 25 cases of benign tertian infection with stovarsol giving up to 4.0 gm. in 5 days; 92 per cent. relapsed. According to Marchoux, the brothers Sergeant, Cluca and Alexa and others, stovarsol is without effect on the parasites of quartan and malignant tertian fever. Some

observers report that its use as an antimalarial remedy has been followed by secondary effects (intestinal disturbances, cutaneous reactions and nephritis), others that it has an excellent action in improving the general health of malarious patients.

Quiniostovarsol. When it was found that arsenical preparations in general have only a feeble action on malaria parasites, it became the custom to combine these remedies with quinine. The mixtures chiefly used are *quiniostovarsol* (Fourneau) and *quinine troposan* (May and Baker). On behalf of the Malaria Commission several workers have made clinical trials with quiniostovarsol. Unfortunately the results reported by different observers are not comparable, because there were great differences in the doses and periods of administration of the drug. The general trend of opinion seems to point to the fact that these drugs are not of much use.

The view held by some observers that *tartar emetic* or other compounds of antimony have an effect on the malarial parasites has now been abandoned, though some of them still hold that they may be useful in preventing relapses.

Mercury compounds such as *perchloride*, *mercurophen*, *mercurosol* and *mercurochrome 220* have been tried in the treatment of malaria without success. They have no curative action in human or avian malaria. In the old days ague was treated with large doses of calomel. It has also been observed that syphilitics, who are saturated with mercury, do not get attacks of malarial fever and for this reason biniodide of mercury by the mouth, in pill form combined with injections of perchloride of mercury has been recommended. The results however are not convincing.

Mercurochrome. Intramuscular and intravenous injections of mercurochrome have been tried in the treatment of malaria. A 0.5 to 1.0 per cent. solution is generally employed, the dose being 0.003 gm. per kilo. body weight. The blood is said to become negative to parasites but this is doubtful. Occasionally it produces flushing, headache and hyperpyrexia.

Coal tar preparations. *Methylene blue*. The use of medicinal methylene blue (methylthioninæ hydrochloridum) against malaria was first suggested by Ehrlich and Gullaman. It has been tried by many observers with varying results. The preparation used should be free from metallic impurities, especially zinc chloride which may cause vesical and rectal irritation. The drug is given in doses of 1 to 4 grains (0.06 to 0.26 gm.) in cachets or capsules 3 or 4 times a day for a week or more, the total daily dose not exceeding one gram. It is excreted in the urine which becomes blue and the stools also turn blue on exposure to air. Many workers have tried it in all forms of malaria without success, while others believe it is a substitute for quinine especially in mild cases of malaria. It is said to be especially useful in

cases refractory to quinine. In the pernicious type methylene blue has been given combined with quinine intravenously, 5 c.cm. of 1 per cent. solution being injected. A dose of 0.2 gm. given in this way followed by neo-arsphenamine four hours later, reduced the relapse rate. Couto (1926) believed that methylene blue is as efficient as quinine in the treatment of benign tertian, but that it had no effect on the malignant tertian parasites. Given subcutaneously it causes abscess formation. Other authorities consider that although it is useless by itself in the treatment of malaria, when combined with quinine it helps to prevent relapses and the therapeutic dose of quinine can be greatly reduced. Recently, it has been tried in doses of 0.2 gm. three times a day at two hour intervals, in the treatment of quartan malaria which does not yield to quinine so readily as the other forms. The author has tried a combination of quinine with methylene blue in quartan infection and considers it superior to many other forms of treatment.

Carbolic acid preparations. Liquid carbolic acid 6 to 12 minims daily for a period varying from 4 to 6 weeks have been tried in the treatment of benign tertian malaria but the results are not promising.

Preparations of hypochlorous acid. *Eusol* or liquor hypochlorous co., which contains approximately 0.027 per cent. of hypochlorous acid was tried in cases of malaria which appeared to be refractory to quinine. Forty c.cm. of a freshly prepared solution were given intravenously, but the drug did not appear to produce any effect either on the parasites or on the fever. Quinine has also been combined with iodine, especially in the treatment of chronic malaria.

Quinine does not act efficiently when the liver is not active. For this purpose it has been combined with such drugs as calomel, rhubarb, aloes. Warburg's tincture contains aloes, rhubarb, saffron, gentian, ginger, cinnamon, camphor, pepper and a number of other things along with quinine sulphate. In doses of half an ounce 2 or 3 times a day on an empty stomach it is quite effective in the treatment of malaria.

Organotherapy. Organotherapy has been used as an aid to quinine treatment. Preparations made from bone-marrow and suprarenal gland have been tried. Bone-marrow extract may be given in the form of tablets, 1 to 3 being given daily, or as a glycerin extract which is sold under the name of 'marrabain.' It has been suggested that low blood pressure in pernicious malaria is due to inefficiency of the adrenal glands and for this reason suprarenal gland extract has been given internally. Injections of adrenalin have also been used for constricting the blood vessels in certain organs and dilating them in others so as to flush them with blood containing quinine. Intravenous injection of adrenalin beginning with 0.01 mgm. and gradually increased to 0.8 mgm. or rarely 0.2 mgm. have been given in the treatment of splenomegaly. As many as 40 injections may be required to reduce the size of the spleen. Dessicated spleen substance has also

been used in doses of 3 to 10 grains daily. Pluriglandular extract, *i.e.*, a combination of suprarenal, spleen, pancreas and thyroid has been used on theoretical grounds.

Radio-therapy. Radio-therapy has been advocated especially in the splenomegaly of malaria, applications being made over the region of the spleen. In chronic cases the effect on the spleen is appreciable. In acute cases heavy dosage is dangerous. Taking into consideration the length of treatment, its difficulties and inconvenience, it should be rejected in favour of quinine and arsenic only.

2. Drugs used against malaria independently of quinine.

A number of medicinal plants have been used in the treatment of ague in India for centuries, but none of them have shown any special effect on the malarial parasites. A brief description of some of these remedies which have been tested by modern scientific methods is given below:—

Vitex peduncularis. This plant grows largely in Bihar, Eastern Bengal and the Central Provinces but it is not very well known. The aboriginal tribes of these localities believe it to have curative properties against malaria, blackwater fever and kala-azar. In Hindi it is known by various names,—*Nagball*, *Nagphani*, *Charaigora*, *Chhagrlaruba*, *Mtn-jurgorwa*, in Bengali it is called *Baruna* and *Goda*.

The only reference by the old writers regarding its medicinal properties is its use for external application for pains in the chest. Vaughan (1921) found that the aboriginal tribes of certain parts of Bihar were well acquainted with this plant, and used it in the treatment of malarial fever and also of blackwater fever. They prepare an infusion of the leaves, of the root-bark or young stems and take it internally several times a day with much benefit. Preference is given to the dark-coloured-root plant over the pale-coloured variety.

Vaughan (1921) tried this drug in a series of cases in both these diseases and reported that it gave very satisfactory results. Chopra, Knowles and others (1924) carefully tested the drug and found it has no effect whatever in malaria.

Peganum harmala. Two alkaloids named *harmaline* and *harmine* occur in *Harmal* or *Peganum harmala*, which grows in abundance in Northern India, possess pharmacological action very similar to quinine. In acute malaria the action is not so pronounced as that of quinine, but harmine is said to have been successful in cases of relapsing malaria where quinine had failed. The writer has tried harmaline in doses of 5 to 10 grains daily without any effect.

Alstonia scholaris. Alkaloids named *ditamine* and *echitamine* are obtained from *Alstonia scholaris*. This plant grows all over India and is said to have strong anti-malarial properties. It has however been found ineffective. *A. congestensis*, *A. macrophylla*, and *A. constricta* are rich in alkaloids and have all been tried.

Berberis aristata. *Berberis aristata* (Rasaut) which grows on the Nilgiris and in the Himalayas contain two alkaloids named *oxycanthine* and *berberine*. Both *Alstonia* and *Berberis* were largely used in India and the eastern colonies in the treatment of malarial fever and are said to have beneficial effects. Waldrop (1927) advocated berberine as a provocative in latent malaria and considered it a specific in splenomegaly. The author tried berberine sulphate in doses of 3 to 4 grains 2 to 3 times a day in the treatment of malaria without success.

Other drugs that have been used in the treatment of ague in the indigenous system in India are *Cæsalpinia bonducella*, *Calotropis gigantea*, *Hydrocotyl asiatica*, *Melia azadirachta*, *Soyimida febrifuga*, *Andrographis paniculata*, *Aconitum napellus* and *Picrorrhiza kurooa* but none of them appear to have any marked antimalarial properties.

Holarrhena antidysenterica. The bark is used in some part of India in the treatment of malaria. The author has tried the alkaloid isolated from the bark, without effect.

Opium and narcotine. Opium is said to assist the action of quinine but there appears to be no foundation for this belief, though it undoubtedly ameliorates the many disagreeable symptoms of this disease. Dr. Roberts (1895) pointed out that the alkaloid *narcotine* or *anarcotine*, which occurs in large quantities in Indian opium possibly has antimalarial properties. As early as 1857 Dr. Palmer treated over 500 cases with narcotine in doses of 1 to 3 grams daily with apparently satisfactory results and for many years this alkaloid was used in the treatment of malaria. Chopra and Mukherji (1930) tried the drug in a series of cases of all forms of malaria, in the Carmichael Hospital for Tropical Diseases, doses ranging from 6 to 12 grains daily and came to the conclusion that this alkaloid has no antimalarial properties whatsoever. Opium addicts taking such large doses of opium as 20 to 30 grains daily get attacks of malarial fever.

A number of proprietary remedies have been recommended for the treatment of malaria.

Smalarina. Six to 8 tablets daily for a month have been tried but are not effective. The drug is liable to produce nausea, vomiting and diarrhoea.

Peracrina 303. According to some, the pills consist of a mass of yeast and a little starch stained with a yellow dye. According to others it is a combination of albumin with 10 per cent. trypanflavin. A course of treatment lasts for 3 months, the maximum dose being 12 pills per day. The drug is expensive and is not effective against an attack nor does it prevent relapses. This substance has been largely used in the treatment of malaria in Russia. It is liable to produce colic, diarrhoea and loss of appetite.

Plaudismol is a yellow liquid with a disagreeable smell and a taste both acid and sweet. It comes from the Argentine and contains extracts of *Senecio salignus*, *Laeselia coccinea* and *Colliandra grandiflora*. It has no therapeutic value in malaria.

Chininphylin. It is quinine salt of mosithexamin phosphoric acid containing 58 per cent. of quinine base; it is said to be as valuable against malaria as quinine.

Elevasan Albert 102 is another one of these remedies.

Urotropine. Malarial coma has been treated with 3.0 c.cm. of a 40 per cent. solution of urotropine intravenously. It is suggested that formaldehyde derivatives hinder adherence of damaged erythrocytes to the wall of the blood vessels and this restores circulation in the blocked vessels.

Fourneau 664 is a compound allied to plasmoquin. It is given intramuscularly and is effective against benign tertian malaria. Doses of 0.04 gm. daily are ineffective and 0.1 gm. is dangerous. The drug is not satisfactory.

Fourneau 712 is a yellow powder soluble in water. It is very active against *P. vivax*, 0.04 gm. daily clearing up the parasites from the peripheral blood. It has no action on the malignant tertian parasites.

R 110 and R. 123 are quinoline preparations. These drugs can be given by the mouth subcutaneously or intramuscularly. They are still in the experimental stage.

CHAPTER XXVI

PRESENT POSITION OF ANTIMALARIAL DRUG THERAPY

The present views regarding the treatment of malaria can be stated by giving the following extract from the Third General Report of the Malaria Commission of the League of Nations (1933).

Treatment of the attack. It has already been indicated that, in an endeavour to treat an attack of malaria successfully, or to assess the relative efficacy of different systems of treatment, various conditions which influence the therapeutic action of antimalarial remedies must be taken into consideration. Among the most important are :—

(1) The species of parasite concerned; (2) the particular geographical race or strain of the parasite; (3) the dose of infection; (4) the stage of the disease—whether it is a primary attack or a relapse; (5) the degree of natural or acquired resistance to malaria possessed by the patient.

Without entering into detail, it may not be out of place to indicate what recent additions to knowledge on these subjects are of importance from the point of view of treatment.

(1) The desirability of investigating separately the therapeutic effect of antimalarial remedies on each of the different species of the parasite is everywhere recognised, and modern practice endeavours, as far as possible, to supply the results in practice. From the point of view of economy in the consumption of quinine, the importance of prescribing a plan applicable to all has become greater since the discovery of *P. ovale*. As a general rule, this parasite is so 'benign' that only one or two small doses of quinine suffice to cure the attack.

(2) About the variations in clinical virulence of different geographical races of the same species of parasite, it may be recalled that, as long ago as 1900, Grassi recognised two distinct clinical varieties of Italian malignant tertian fever, and named one of them *mitis*, which means mild, to other *immitis*, which means severe. Since then, many observers have noted remarkable differences between the malignity of malaria caused by *P. falciparum* in different parts of the world. From one part of British India it has been reported that *P. falciparum* in its schizogony cycle is the most amenable of the three species to quinine therapy, while from another part quite the contrary opinion has been recorded.

In recent years, a study of this subject in cases of human malaria intentionally infected with known strains of *P. falciparum* from different countries has yielded interesting results. It has been found for example, that, to control the primary attack of malignant tertian malaria infected with a Rome strain of *P. falciparum*, it required eight times as much quinine as was required to control cases infected under precisely the same conditions with an Indian strain. Again, it has been found in the Netherlands that various geographical races of *P. vivax* react differently to the same remedy. These and other results afford a reasonable explanation of contradictory observations on the therapeutic efficacy of the same plan of treatment conducted in different countries, and indicate the importance of local therapeutic investigation. Field workers and hospital physicians in all malarious parts of the world should endeavour as soon as possible to add to existing information the clinical virulence and amenability to quinine of the particular strains of *P. falciparum*, and of other species prevalent in the countries where they work.

(3) What influence the dose of infection may have in relation to the therapeutics of malaria is a problem about which little information is as yet available. In general, it is believed that primary attacks of malaria caused by the bites of many mosquitoes are more difficult to control by quinine than are primary attacks caused by the bite of only one or two insects. In this connection, an important result of experimental work is that it has been found possible, by causing many mosquitoes infected with *P. ovale* to bite the same person repeatedly over a period of several days, to produce even with this very benign parasite a severe clinical and parasitological attack, for which specific treatment must be promptly given.

(4) and (5). For selecting the best treatment in a case of malaria, nothing is more important than a knowledge of the stage of the disease. Quinine has no appreciable effect when given during the incubation period, and it has little effect when given on the first or even on the second day of the 'initial fever'. It is much more effective after the patient has had several paroxysms of fever than at an earlier stage, and its effect is greatest when the fever and parasites are beginning to decline as a result of the natural defensive mechanism which normal human beings possess. A relapse is always more amenable to quinine than a primary attack. The reason why a cure is more easily brought about by quinine in the later than in the earlier stages is that persons who pass safely through a few paroxysms quickly acquire a defensive property, which counteracts to a great extent the harmful effects of the parasite. The practice of malaria-therapy has thrown a good deal of light on this subject by showing that persons who have passed through ten or more severe paroxysms of benign tertian malaria without receiving any quinine have already acquired such a high degree of natural

defensive power that a few small doses of quinine suffice for the temporary cure of the attack. Treatment should aim at assisting malarial patients to acquire as much as possible of this defensive power (sometimes called 'tolerance,' 'immunity' or 'premunition'). With this object, an endeavour should be made to ascertain precisely the stage of the patient's disease, and to prescribe the doses of quinine which are just sufficient to be effective in that particular stage, without at the same time interfering with the patient's defensive mechanism. To give large doses of quinine indiscriminately to all cases of malaria is a grave error. The selection of the correct dosage for particular stages of malarial attacks, with due attention also to the species of parasite concerned and the virulence of the local strain, is an important item in the modern method of treating malaria. It will be mentioned again when describing general rules for treatment by quinine. All we wish to do here is to correct the common view that the earlier one begins specific treatment, the more successful will be the results. Except in very severe cases, in which the patient is almost overwhelmed by the parasitic invasion, and is therefore unable to acquire any defensive power against it, the truth is just the reverse. The same remark applies to relapses. It is a common belief that relapses are difficult to cure because they are late manifestations occurring in persons who have not been treated early in their primary attack, or who have been insufficiently treated with quinine in that attack. The truth is that relapses are always much more easily controlled than the primary attacks, because the patient already possesses some acquired defensive power. Indeed, as was pointed out long ago by Koch, Marchiafava and others, the risk of pernicious symptoms in malignant tertian fever is greatest in the primary attack and early recrudescences, because any person who has recovered from that stage of the disease has acquired sufficient defensive power ('tolerance' or 'premunition') to protect him, when he gets a relapse, against those disastrous occurrences.

General rules for treatment of the attack. Before dealing with the specific drug therapy of malaria, it is desirable to mention briefly some general rules to which attention must always be given if success in treating attacks of the disease is to be obtained. It is to be understood, however, that no attempts will be made to deal with this subject completely, or to indicate the treatment of complications such as heart-failure, delirium, very low blood-pressure.

The Commission wishes to emphasize the importance of insisting that persons who are liable to suffer from malarial attacks should go to bed as soon as they feel that an attack may be impending. In many cases there are premonitory signs, and it often happens that patients who go to bed with the onset of these signs, and take a purgative, followed by a therapeutic dose of quinine, can ward off the attack or escape lightly. The endeavour should be to get the patient

comfortably to bed, and in a condition which favours perspiration before the actual paroxysm of shivering begins. In most cases, it is sufficient for the patient to get under blankets with hot-water bottles, and to take first a full dose of a simple diaphoretic mixture, and then a cup of hot broth or tea.

Having made the patient as comfortable as possible, the condition of the stomach and bowels requires attention. Patients suffering from malaria are almost invariably constipated, and this condition must be corrected as early as possible if quinine is to produce its maximum effect. It will have to be decided whether it is practicable in the particular case to begin with clearing out the lower bowel by an effective enema; if this can be done, the patient will afterwards be much more comfortable, and less likely to suffer from nausea and vomiting. A drug should next be given which will act upon the liver, and will induce a free flow of bile, which is a good solvent of quinine. It must be followed within a few hours by a saline draught, and a dose of natural aperient water should be repeated each morning throughout the attack.

Next, attention should be given to the exact diagnosis of the type of malaria and the particular stage of the disease, with a view to deciding with what specific antimalarial remedy and in what doses, treatment will be begun. This subject (specific drug therapy) will be considered in a later paragraph.

Lastly, in addition to specific treatment, attention should be given to an endeavour to allay particular symptoms. Of the numerous drugs which have been tried for obviating cinchonism, it is said that caffeine given hypodermically or intravenously shortly before the administration of quinine, is the most effective. To relieve headache, phenacetin and similar drugs are often given, but they should be used with caution on account of their depressing effect on the heart. Headache is often greatly relieved when the bowels have been cleared by an enema. For nausea, a full dose of bicarbonate of soda taken in hot water and repeated at intervals is sometimes useful. *In all cases with severe vomiting, and in all cases in which there are signs of cerebral or other dangerous complications, a dose of the specific remedy should be given intravenously.* Quinine bishydrochloride 0.6 gm. dissolved in 5 c.cm. of physiological salt solution is a suitable dose for intravenous medication. Until it has taken effect the patient should be given ice to suck.

General management. During the hot stage, the temperature and general condition of the patient must be carefully watched; but knowing that in all probability the high temperature will not last long, it is less necessary to take very active measures to reduce it than in the continued fevers. Temperatures of 104.5° or 105° F. (40.3° or 40.6° C.) are common in benign tertian malaria, and need occasion no alarm, but a tendency to rise higher than this should be counteracted by tepid or cold sponging. If possible, however, we should do nothing which may delay the onset of the sweating stage, in which the patient gets almost

immediate relief. Shortly after the onset of this stage, the patient's wet clothing should be changed, and he may be given a stimulating drink. Usually, he will go to sleep for an hour or two, and wake in a bath of perspiration and very weak, but feeling that, at any rate for the time, his illness is over. When the hot stage lasts a long time, and there is distressing headache or restlessness, a hypodermic injection of morphia is the best treatment. While there is fever, the patient should drink as much fluid as possible (preferably soda-water, barley-water, and other alkaline drinks), and in all cases the urine should be examined frequently for albumin, blood and haemoglobin. Albuminuria is often only temporary, but if casts are present in the centrifugalized deposit, it must be regarded as a serious complication requiring careful dietetic, nursing and medicinal treatment.

Lastly, among these general rules the Commission desires to make the following remarks about the administration of the specific remedies :—

(1) The manner in which quinine acts in bringing about a disappearance of fever and parasites is not known, and this seems to be true also for the new synthetic remedies. But there is a general consensus of opinion that, to obtain the optimum action of specific anti-malarial remedies, the co-operation of the host's defensive mechanism is necessary, and that this mechanism may be greatly impaired—or, indeed, may be suppressed entirely—by giving the specific drugs in too large doses or during too long a period. As regards quinine, it has been proved that large doses are not more effective than moderate doses. On these grounds the Commission considers that large doses of quinine (and presumably of the new synthetic remedies) should be avoided, and that courses of treatment with curative doses should not exceed seven days and that treatment for five days will often suffice.

The Commission also wishes to say that, although it recommends that quinine should be administered intravenously in acute cases with dangerous symptoms, it strongly disapproves the practice of treating ordinary cases of malaria by intravenous or intramuscular injections of quinine.

(2) It thinks, also, that, after the clinical cure of a primary attack (which means, as a general rule, after curative doses have been administered for five to seven days), it is best to cease giving the specific drug for a time, in order that the secondary effects of the drug on the human body may entirely pass off. A person whose primary attack has been cured by a course of five or seven days' treatment with therapeutic doses of a specific remedy will certainly remain free from a recrudescence for at least a week, and no advantage whatever is derived from continuing to give the specific drug during that fever-free and parasite-free period. Neither treatment with quinine nor with any of the new synthetic drugs, however intensive the treatment may be, is a *therapia magna sterilisans*, and the same effect in preventing recrudescence

cences and relapses is obtained when an interval of a week or ten days is allowed to elapse between the end of the curative course and the beginning of the prophylactic course, as is obtained when the specific drug is administered continuously during that period.

(3) The Commission is of opinion that it is seldom or never in the best interests of patients to endeavour to combine a plan of treatment designed for the prevention of relapses with a plan having for its object the rapid clinical cure of an acute attack. In particular, they wish to suggest that caution should be exercised in adopting the practice of combining plasmoquine with quinine or with atebtrin in the treatment of acute primary attacks. Plasmoquine in non-toxic doses is not considered to have an effective action on the asexual (fever-producing) stages of the malaria parasite (particularly *P. falciparum*), and the Commission suggests that, until more is known of its toxicity to patients who are suffering from high fever, and who are liable to have cerebral or cardiac complications, its administration should be deferred until the primary attack has been overcome.

Specific drug therapy. In addition to quinine and other preparations of cinchona bark, two synthetic preparations—namely, plasmoquine and atebtrin (formerly named erion)—must now be classed as specific antimalarial remedies, which are being extensively used in many parts of the world. They are not to be regarded as substitutes for quinine, but as additional weapons for use in particular circumstances and for special purposes. What has to be understood and to be applied in practice is that each of the three specific drugs—quinine, plasmoquine and atebtrin—has its own particular action on the malaria parasite in one or other phase of its life-cycle in the human host, and that what the physician should aim at is to select the correct drug and the optimum dosage for the particular purpose which he has in view. The particular purpose to be dealt with in this section is treatment of the malarial attack.

In considering this subject, it is important, in the first place, not to bring confusion into the problem by assuming that the physician who sets out to cure an attack of malaria must at the same time occupy himself with the task of preventing relapses. The two purposes (cure of the primary attack and prevention of relapses) are so entirely different that, in the opinion of the Commission, it is incorrect to endeavour to accomplish them both at the same time. The first object to be accomplished is to cure the attack from which the patient is suffering; when that has been done, attention can be given to the problem of relapses. These remarks are made because, in the opinion of the Commission, it is not a good practice to treat attacks of malaria in the acute stage with a combination of two of the specific drugs mentioned, in the hope that one of them will be effective in curing the attack, the other in preventing relapses. Particularly with regard to the growing practice of treat-

ing acute attacks with a combination of quinine and plasmoquin, the Commission's attention has been drawn to observations indicating that the toxic effects of plasmoquin seem to be enhanced by a condition of fever and anaemia. It is known that at least in malignant tertian fever plasmoquin is not effective against the asexual (fever-producing) stages of the parasite and it is suggested that the administration of this supplementary remedy should be deferred until the acute stage of the disease has been overcome.

Taking up the position, then, that the best practice in treating an acute attack is to employ only one specific drug, it has to be decided for the particular case concerned which of the three is to be preferred, and in what doses the selected drug is to be used.

At the present time, this question can be answered categorically for only one type of malaria—namely, *malignant tertian* fever caused by *P. falciparum*. There is a general consensus of opinion that, for treating primary attacks of this type of malaria, atebirin is very much more effective than quinine or any other remedy hitherto known. The usual doses are three tablets (each containing 0.1 gm.) daily by the mouth for five or seven days. As the drug is relatively non-toxic, a dose of six tablets (0.6 gm.) can be given on the first day if desired. In cases with severe vomiting or other complication which prevents oral administration, the drug can be given intravenously or intramuscularly in solution. It dissolves readily in normal saline. A suitable dose for intravenous administration is 0.3 gm. dissolved in 5 c.cm. normal saline. But the practice recommended by Professor Nocht and Professor Muhlen for treating severe cases is to begin with one or more intravenous injections of quinine, followed on the next and subsequent days by oral administration of atebirin. The opinion that atebirin is superior to quinine for the cure of primary attacks of malignant tertian malaria rests upon a large number of reports relating to natural cases treated in hospitals in the field, and also upon carefully controlled therapeutic experiments made in circumstances in which all the conditions were known.

It is to be understood, of course, that, in expressing the opinion that atebirin is the best of available antimalarial remedies for treating primary attacks of malignant tertian malaria, the Commission does not imply that good results cannot be obtained with quinine. In some parts of the world, the common strain of *P. falciparum* is of such low virulence that even small doses of quinine suffice for its cure. For example, as regards the strain which is common in one part of India, Knowles and his co-workers have said: "*P. falciparum* in its schizogony cycle is admittedly the most amenable of the three species of malaria parasite to quinine therapy." Experimental studies of cases infected intentionally with a strain from the area to which those observers referred have shown that, on an average, of the amounts of quinine used

in twenty cases, only 3 gm. of quinine given by the mouth, and spread over a few days, were required to cure the primary attacks and to prevent, in 25 per cent. of the cases, any subsequent relapse. A strain which is equally non-virulent appears to exist in some localities in West Africa. On the other hand, there are parts of India and Africa, as well as of Italy and other countries, where quinine is relatively quite ineffective against the local strain. It is in these localities particularly that the use of atebirin is desirable.

The answer to the question, 'Which is the best drug to select for treating primary attacks of benign tertian fever?' cannot at present be stated so definitely. In many countries, the prevalent local strain of *P. vivax* causes a relatively 'benign' primary attack with a tendency towards recovery, whether it is treated with specific drugs or not. Many statistical records of the percentage of cases of benign tertian malaria which in particular countries recover without specific treatment are available in the literature; Osler's estimate of 20 per cent. is often quoted. That different strains of the parasite are more or less susceptible to the action of specific remedies must now be regarded as having been established, and the knowledge makes it very difficult to compare the records of different observers satisfactorily. Probably the most virulent strain which is being worked with experimentally in the practice of malaria-therapy in Europe at present is the Madagascar strain used in mental hospitals in England since 1925, and also now being used in the Netherlands, Italy, Germany and Malta. Persons infected with this strain have to be kept under constant medical attention during the course, and must almost invariably be treated with a specific remedy when it is considered that they have passed through a sufficient number of febrile paroxysms. In hospitals where there is insufficient watchfulness and attention to the blood condition, the fatality due to this strain of benign tertian malaria is not less than 10 to 14 per cent. The comparative value of quinine bihydrochloride, atebirin and plasmoquin for treatment of primary attacks of benign tertian malaria caused by this strain has been examined by the method called 'abortion of the attack'. As between the therapeutic effect of quinine bihydrochloride and of atebirin when given at the same stage of the primary attack, not much difference can be observed. A single dose of atebirin (0.6 gm.) given between the seventh and tenth day of the attack will cause all the parasites to disappear, and the fever to cease within less than thirty-six hours, but a single dose of 0.6 gm. quinine bihydrochloride will produce the same good result. A more precise comparison of their relative efficacy could be made by using very small doses; but, as it is seldom or never the practice of physicians to use small doses of quinine for therapeutic purposes, the results would have little practical value. It appears from trials of atebirin and of quinine for the purpose of 'clinical prophylaxis' that in reality, a dose of 0.1 gm. of atebirin has

more effect in benign tertian malaria than a dose of 0.3 gm. of quinine, but therapeutic practice differs from prophylactic practice in that in the former it is a custom to use larger doses than are, believed on scientific grounds to be sufficient. And when one uses a drug in doses larger than are necessary to effect the purpose desired, small differences between the comparative effect of different antimalarial remedies are not apparent. It has been shown definitely, for example, by comparative therapeutic tests under experimental conditions, that, in benign tertian malaria, no better effect can be detected when a dose of 2 gm. quinine (30 grains) is administered than when the dose is only 1.2 gm. (20 grains). For the same reason if, in comparing the therapeutic efficacy of quinetum with the therapeutic efficacy of quinine, one were to use daily doses of 30 grains (2 gm.) one would arrive at the conclusion that the therapeutic effect of either of those mixtures of alkaloids is equal to that of quinine. But by using minimum instead of maximum doses, it would be found that that conclusion is wrong. Apparent equality of action in tests with large doses results from the fact that the dose of mixed alkaloids although it does not contain 30 grains (2 gm.) of quinine, contains this alkaloid in sufficient quantity to produce the same therapeutic effect as is observed to result from its administration in that dose.

On these considerations the Commission does not consider that, for the treatment of primary attacks of benign tertian malaria, preference should be given to atebirin rather than to quinine. In the doses usually recommended, both are invariably efficacious. Each has some disadvantages, but they are trivial in comparison with their merits as antimalarial remedies. If it is desired to compare the relative cost of the two drugs for treatment of primary attacks of benign tertian malaria, the comparison should be between the cost of treatment comprising 1 gm., or at most 1.2 gm. (20 grains), of quinine bihydrochloride or quinine hydrochloride in tablets daily for five days and 0.3 gm. atebirin in tablets daily for five days. Using quinine, it is seldom necessary in benign tertian malaria to prolong the period of treatment of the primary attack beyond five days. For this reason the comparison should be with atebirin treatment for the same period.

So far as is known at present, the answer to the question "which of the specific drugs is best for the treatment of primary attacks of quartan malaria?" is much the same as that regarding benign tertian malaria—namely, that, because either of the remedies, quinine and atebirin are almost always effective, the choice between them must be decided on other considerations than those of immediate therapeutic efficacy for the clinical cure of the primary attack. A few cases of quartan malaria are surprisingly resistant to quinine, and it may be found that a few are resistant to atebirin. When one drug fails, the other should be tried.

In consideration of what has just been said, the Commission desires to suggest that the principal fact which should be kept in mind and applied in the practice of treating primary attacks of malaria is that two specific remedies instead of only one are now available. Neither of them complies with the requirements of a *therapia magna sterilisans*, and it would not be wise in the Commission's opinion, to decide that, for general routine use, one of them should be preferred to the other. The great advantage of possessing two curative drugs is that, in cases which seem to be resistant to treatment with one, trial of the other can be made. This, of course, is what should be done in practice. Everyone with experience of malaria in the tropics has encountered exceptional cases even of benign tertian or of quartan fever in which parasites can be found in the blood longer than five days after beginning a curative course of quinine, which usually results in causing all parasites to disappear by the second or third day. Such cases are those in which trial of the other specific might give a better result. The reverse is equally true. In a recent unpublished paper, Green working in Malaya, reports that, as yet he is not able to come to a final decision on the comparative efficacy of quinine and atabrin for the treatment of primary attacks of malignant tertian malaria. In one series of cases suffering from attacks caused by this type of malaria, ring forms of the parasite persisted in quinine treated cases for, on an average 2.8 days, and in atabrin treated cases 3.5 days. In a later series, ring forms persisted, on an average, in quinine treated cases 3.1 days and in atabrin treated cases also 3.1 days but it was said that in this series, the degree of infection in the atabrin treated cases was on the whole, lighter than in the quinine treated cases.

The use of plasmoquine in primary attacks. Nothing has been said as yet about the use of plasmoquine instead of quinine or atabrin for the clinical cure of primary attacks. For several years after its introduction plasmoquine was tried extensively for that purpose in doses of from 0.06 to 0.1 gm. or more daily for five days, and in some trials for much longer. It was reported in general that, in those doses, the therapeutic effect of plasmoquine for curing primary attacks of benign tertian and quartan fever was about equal to that of quinine, but that for curing primary attacks of malignant tertian fever its effect was by no means so good. It was found, moreover, that toxic symptoms were the general rule when those doses were employed, and that it was frequently necessary to reduce them or to suspend the treatment for a time. In a thorough trial with doses not exceeding 0.06 to 0.08 gm. daily, which was conducted on natural and induced malaria in Roumania in 1931, it was found necessary to suspend the treatment in 60 per cent. of the cases chiefly on account of cyanosis, excessive fatigue, profuse perspiration and cardiac troubles accom-

panied by attacks of vertigo and fainting. In a trial in India, suspension of treatment was necessary in twenty-two of twenty-nine cases, and it was found that some patients are more susceptible to the toxic effects of the drug than others; very strict medical examination of all patients at least once a day was considered to be necessary. Similar, and occasionally more serious, findings were reported from other countries, and as a result, it became a general rule not to use the drug for therapeutic purposes in larger doses than 0.04 gm. per diem. A common practice at present is to use it in even smaller doses (0.02 gm.) in combination with quinine. In these small doses it has little or no curative action on the asexual (fever producing) stages of the malaria parasite, and for this reason its use in the acute stage of a primary attack is difficult to justify. It was thought at first that a small dose given daily in the acute stage might prevent the development of the sexual forms of the parasite, which appear as a rule about the seventh day of the primary attack; but it has been found that the onset of crescents in the peripheral blood is not prevented or retarded even by larger doses of plasmoquin than it is customary now to give.

SECTION IV

REMEDIES USED AGAINST SPIRAL ORGANISMS

The spiral organisms commonly met with in man can be grouped under the following heads:—

(1) **Spirillum**. This organism has got a rigid structure and the coils are preformed with terminal flagellum at each end.

(2) **Spirochæta**. This has a flexible structure and the coils are not preformed. The presence of flagella at the ends is doubtful.

(3) **Treponema**. Here the coils are very small, smooth and uniform with finely pointed ends.

(4) **Leptospira**. The primary coils in this organism are closely set and minute. It looks like a brilliantly refractile swimming bit of rope. The secondary coils are loose and open and with a tendency to loop at both ends.

The name spirochæte is employed as a general term for certain spiral organisms which have flexible bodies. The structure, morphology and nomenclature of these organisms are not definitely known. Schaudinn (1904) considered them to belong to the protozoal group. The work of Minchin and Woodcock (1911) and of the brothers Sargent (1907) has refuted the original hypothesis of Schaudinn. Dobell has grouped the spirochætes among the bacteria. As the position with regard to their classification is far from clear, the spirochætes will be considered in a separate section altogether.

The pathogenic spiral organisms of man may be classified as follows:—

1. *The blood-inhabiting spirochætes, viz., those of the relapsing fevers, and Spirillum minus, the parasite of rat-bite fever.*

2. *The Leptospira group including the parasites of Weil's disease, and Japanese seven-day fever.*

3. *The Treponema group including the spirochætes of syphilis and yaws.*

4. *Vincent's spirochæte, which together with the fusiform bacillus is responsible for Vincent's infection.*

The Relapsing fever spirochætes. The spirochæte of relapsing fever was first described by Obermeier (1873) and was named *Spirochæta Obermeieri*. Since then a large number of different species of the relaps-

ing fever spirochaetes, e.g., *S. recurrentis*, *S. duttoni*, *S. carteri*, have been described by workers in different parts of the world. It is very doubtful, however, whether these so-called species represent anything more than local races of one and the same spirochaete. Many distinguished workers have shown that it is impossible to distinguish the various strains from their morphological characteristics. It is better, therefore, to conclude that there is but one species of relapsing fever spirochaete, *Spirochaeta recurrentis*. The organism, when observed alive under dark ground illumination, shows the axis of its spiral nearly always straight and its coils uniform. When an infection is abating as the result of the development of antibodies in the blood, various coiled and clumped organisms may be found. In stained films, the spirochaetes show a very irregular appearance with widely open coils, twists, and every possible variation in type.

Spirillum minus, the cause of rat-bite fever, is commonly met with in India. This organism is found in the blood of infected mice, rats or guinea-pigs during the first two weeks and then becomes distributed in the connective tissues of the lips, nose, and tongue. It has been found that about 3 per cent. of house rats are carriers of the disease.

The Leptospira group. These organisms are characterised by the fact that the body consists of a spirally wound thread, the spirals being so fine that unless careful inspection is made they are overlooked. Under the dark-ground, the leptospira look like brilliantly refractile swimming pieces of rope. The two diseases due to leptospira infection in man are:—(1) Weil's disease due to *L. icterohæmorrhagica*, (2) Japanese seven-day fever due to *L. hebdomadis*.

Treponema pallidum. The spirochaete of syphilis has essentially the same structure as the relapsing fever spirochaetes, from which it differs only in being smaller and in having a larger number of coils for a given length. These are essentially parasites of the tissues and of the lymphatic system and include the following species:—(a) *Treponema pallidum*, the spirochaete of syphilis, (b) *Treponema pertenue*, the spirochaete of yaws, and (c) *Treponema cuniculi*, a spirochaete of the rabbit.

The discovery of the spirochæticidal power of arsenic and its derivatives marks the dawn of a new era in chemotherapy. The researches of Ehrlich and many other renowned workers that followed him were directed primarily to fight the organism of syphilis, i.e., *Spirochaeta pallida*. The success attained in this direction has practically solved the problem of spirochæta infections in all its protean manifestations.

CHAPTER XXVII

ARSENIC AND ITS DERIVATIVES

Arsenic is very widely distributed in nature. Some of the less active preparations of arsenic such as the sulphides, realgar (As_2S_2) and orpiment (As_2S_3) have been known in therapeutics since the beginning of the Christian era, but arsenic compounds were only brought into special prominence very much later when Geber in the Middle Ages prepared the active oxide, commonly called white arsenic (As_2O_3). Although arsenic was first used in medicine in England in the early part of the 17th century, its authentic history does not begin till Sir Thomas Fowler introduced Fowler's solution in 1786. Its employment in the treatment of protozoal diseases was first suggested by the famous explorer, Dr. Livingston as he recommended its use in the disease caused by the tsetse fly in animals.

Arsenic has been largely employed in art and commerce and on account of its ready accessibility it has been used for suicidal and homicidal poisoning. It was also used for spraying vines and other plants to protect them from attacks of insects and pests; but this had to be given up owing to its appearance in the wines produced from the plants so treated.

PHARMACOLOGICAL ACTION

Arsenic is toxic to all animals which possess a central nervous system and to most of the higher plants, but not to all lower organisms. Its antiseptic action is feeble and it is not classified as a protoplasmic poison. In 1 in 30,000 parts of water arsenic hinders the development of and eventually kills the algæ and the seeds of higher plants; moulds grow abundantly in 1 per cent. solution of potassium arsenite; alcoholic fermentation proceeds in the presence of arsenic although somewhat retarded at first. Arsenious acid is only one-tenth as strong an antiseptic as perchloride of mercury. Compounds of arsenic have no effect on the activities of such ferments as pepsin. Some of the pathogenic protozoa, e.g., trypanosomes, show a most extraordinary susceptibility to arsenic and are destroyed in 1 in 200,000 dilution in the blood, while

free-living protozoa may survive in 1 in 5,000 solution. Malarial parasites are markedly resistant to the action of arsenic.

Local action. Arsenicals do not coagulate proteins nor change them in any way and, therefore, they produce very little irritation of raw surfaces and mucous membranes, but the cells die slowly after prolonged contact with them. They are for this reason used for destruction of exposed dental nerves and epithelial growths of the skin. When applied to mucous membranes and denuded surfaces, they produce much pain and deep destruction of the tissues. Arsenical dermatitis occurs among workers who handle it.

The unbroken skin is not affected by arsenic unless it is repeatedly applied or allowed to remain in contact with it for some time, when it may produce pustules or vesicles. In man, arsenic has a beneficial effect on the nutrition of the skin; the subcutaneous fat is increased and the complexion is improved; it renders the coat of domestic animals such as the horse thicker and more glossy. In veterinary medicine it is commonly used for this purpose and solutions of arsenic are used as 'dip' to rid animals of ticks, etc. Large doses cause eruptions and keratosis, but this is not due to vaso-dilator effects nor is there evidence of any action on the nerves. Arsenic compounds undoubtedly, during their excretion, have a marked action on the intestinal epithelium and it is probable that they also exert a specific action on the epithelial cells of the skin. The arsenicals also produce a brown colouration of the skin of the face and other parts which is known as 'melanosis'. This is not due to the deposition of an arsenic compound, but of some organic product in the deeper layers of the corium.

Alimentary canal. Small doses such as one-sixtieth to one-fiftieth of a grain of the oxide are said to increase the appetite and aid digestion; larger doses irritate the whole of the gastro-intestinal tract producing swelling and congestion of the mucous membrane. The mucous membrane of the stomach is generally red and swollen and often contains hæmorrhagic patches. One-fourth to half a grain produces gastric pain, nausea, vomiting and diarrhœa; after two or three grains the alimentary symptoms are much more intensified. Capillary paralysis is produced causing much exudation into the connective tissue; the epithelium is at first raised and can be easily rubbed off; then it is cast off as shreds or false membrane. The epithelium may also show cloudy swelling and fatty infiltration, and in some cases these are the only lesions present. The exudation poured into the lumen of the gut causes distension, increased peristalsis and profuse rice water stools; collapse and death may follow. These symptoms occur whether arsenic is given by the mouth or subcutaneously, though slightly larger doses are required by the latter route. The action on the alimentary canal is not of a corrosive nature but is a specific effect and there is a definite latent period.

Circulation. Very small doses have no effect on the isolated frog's heart, large doses depress it; the amplitude is at first increased but soon it is diminished; the rate may be slowed or quickened or become arrhythmic, the heart stopping in diastole; the effect seems to be a direct one on the cardiac muscle. The mammalian heart is little affected but large doses intravenously produce a fall of blood pressure due to paralysis and dilatation of the capillaries. This action on the capillary endothelium is direct as adrenalin and nicotine continue to raise the blood pressure after arsenic. Arsenic is thus termed a capillary poison. The vessels of the splanchnic area seem to be more susceptible to the action of arsenic than those of the rest of the body. Their dilatation leads to congestion of the bowels, fall of blood pressure and collapse. It has been experimentally shown that the capillaries are injured and become more permeable after arsenic poisoning. Intravenous injections of large quantities of saline cause oedema in animals to whom toxic doses of arsenic compounds have been given, while no such effects are produced in normal animals.

In therapeutic doses in man, little direct effect is produced. If continued for a long time, failure of the heart's action occurs as manifested by oedema of the feet, diminution in the quantity of urine and feeble, low-tension pulse. Degenerative changes in the heart muscle resembling those occurring in phosphorus poisoning have been shown to occur. The pronounced and persistent fall of blood pressure is partly due to cardiac failure and vasomotor depression, but chiefly to paralysis of capillaries. The flow of lymph in the thoracic duct is said to be increased by arsenic.

Blood. It is on the blood-forming organs that arsenic is believed to produce its most beneficial effects. The action is still obscure though it is largely prescribed in anæmia. Arsenic probably produces increased vascularity and stimulates the bone-marrow to increased formation of erythrocytes and hæmoglobin when anæmia exists. In pernicious anæmia it is said to increase the number of young newly formed red cells. With ordinary therapeutic doses however, no changes either in the erythrocytes or the hæmoglobin content have been observed in normal individuals nor in those suffering from chlorosis. Intravenous injections of organic arsenicals have no influence on the total or differential leucocyte count unless toxic reactions occur. A slight increase may occur sometimes a few hours after injection but at the end of 24 hours the count is again normal. In larger doses there is extensive degeneration of the cells of the bone-marrow and anæmia is produced.

It has been shown that in shed blood, small quantities of arsenites protect the red cells from various hæmolytic agents, and this may partly explain its beneficial action in diseases like pernicious anæmia. Experiments show that the presence of sodium arsenite in a concentra-

tion of 1 in 20,000 stops the hæmolytic action of distilled water or other toxins on washed red blood corpuscles, *in vitro*. In therapeutic doses arsenicals have no effect on the coagulability of the blood.

Respiration. Small amounts have a distinct stimulating effect on the respiratory centre; large amounts depress it. In arsenic poisoning in man the respiration is not affected until very late, but ceases before the heart, probably on account of the exhaustion of the centre from low blood pressure. Small doses are said to depress the peripheral terminations of the vagi in the lungs; hence it is used in asthma.

Central nervous system. In the frog a descending paralysis is produced, the animal first losing its spontaneous movements and then its reflexes; the terminations of the motor nerves become affected later on. In the mammal, no certain indications of any such action are forthcoming as paralysis and coma can be explained by the gastro-intestinal effects and capillary changes. In chronic poisoning, peripheral neuritis and characteristic lesions in the nerve trunks occur in man and animals and in severe cases the spinal cord may be secondarily involved.

Metabolism. With small doses there is increased assimilation and decreased katabolism which give rise to improved digestion and increase in the body weight; metabolism of carbohydrates is slowed and fat is deposited. If large doses are given it causes increased breakdown of tissues as shown by augmented excretion of nitrogen, sulphates and phosphates in the urine. It is not clear whether this increase is due to urea or other constituents, but probably ammonia is increased. The glycogen in the tissues is decreased, lactic acid is markedly increased; the available alkali of the blood is reduced and the alkalinity of the tissues is diminished. There is destruction of blood cells causing anæmia and fatty changes in different organs. Small necrotic areas are found in the liver and jaundice may occur. These effects are attributed to diminished oxidation of the tissues owing to the direct action of arsenic on the cytoplasm of the cells. The popular view is that the growth of young animals is stimulated by arsenic, but recent investigations have shown that this is not the case.

The change in nitrogen metabolism is very small. Excessive doses lead to loss of weight, fatty degeneration of organs and destruction of blood cells.

Fate in the body. Arsenic is absorbed readily even from the unbroken skin and mucous membranes. Poisoning may therefore result from the external use of arsenical cosmetic preparations. After hypodermic injection of large doses, diarrhoea may start within an hour.

Normal occurrence of arsenic in the body. It must be borne in mind that arsenic is a normal constituent of the human tissues, this was originally discovered by Gantier, (1899) and confirmed by Bertrand (1902-3) and others (1923-5). Arsenic present in the tissues normally

plays no part in their functions. In man it occurs especially in the thyroid gland (0.16 mgm.), in the thymus, brain, skin and hair; in the blood it has been estimated to be present to the extent of 0.3 mgm. per 100 c.cm. of a dried specimen. Arsenic to the extent of 0.3 mgm. has been found in 100 gm. of dried normal urine. It is found in milk after administration for medicinal purposes and through the milk it passes from the mother to the infant. Large amounts of arsenic are found in the lungs in pneumonia and cardiac disease. The arsenic occurring in the tissues normally is introduced with foods such as milk, eggs, fish, vegetable, wines, and also in drinking-water. It was estimated that in Paris every person receives about 7.66 mgm. annually. According to the Royal Commission of 1903 the quantity of arsenic in the food should not exceed 1/100 gr. per pound. Arsenic is invariably present in varying amounts in many medicinal agents. From the medico-legal point of view the quantity of arsenic normally present in the intestinal canal never exceeds 1/10 mgm.; larger quantities indicate poisoning or administration in the form of medicine.

Excretion. Arsenic disappears rapidly from the blood when injected and is fixed in certain tissues. It is chiefly found in the liver, kidneys, walls of the stomach and intestines, in the spleen and lungs. Much smaller quantities are found in the muscle and nerve tissue. With oral administration the main part leaves by the fæces; with hypodermic injection, by the urine. When arsenious acid or arsenites are given by the mouth or injected, they are excreted slowly, less than 20 per cent. appearing in the urine in the first twenty-four hours and a similar quantity in the fæces. After a single dose excretion of arsenic goes on for ten days, and after repeated doses it may continue for months. The arsenic retained is distributed in the tissues. It is also found in the hair and epidermis for months after its disappearance in the urine and fæces; traces may occur in other secretions.

Tolerance. If an animal is given daily doses of arsenic in gradually increasing quantities, after some months the usual lethal dose may be given without any symptoms of poisoning being produced. A similar tolerance can be established in man. The inhabitants of Styria consume arsenic in large quantities, as a general stimulant and to improve their complexions. As much as 7 or 8 grains (0.5 gm.) a day of the oxide are taken without apparent harm. It is said to produce intoxicating effects, stimulation of sexual and respiratory functions and a feeling of strength and well-being. Withdrawal does not cause any abstinence symptoms.

The phenomenon of tolerance to arsenic has not been satisfactorily explained. Some consider that the tolerance is limited to the intestinal epithelium, which no longer undergoes inflammation and necrosis under arsenic and absorbs less of this drug. Considerable quantities of arsenic, however, occur in the urine of arsenic eaters and therefore

absorption must occur. Another hypothesis is that an antitoxin is formed, while yet another explanation given is that non-ionisable organic compounds are formed in the body. Tolerance is sometimes acquired by the pathogenic protozoa, and arsenic-fast strains of trypanosomes have been experimentally produced. This apparent drug fastness has been attributed to two factors:—(1) deficiency of the host's tissues, (2) a nidus for the parasites in the tissues impervious to the drug.

Inorganic Arsenic compounds. All inorganic compounds of arsenic are very poisonous but metallic arsenic is insoluble in water and passes through the alimentary canal, for the most part unchanged and without exerting much action. It is probable that the activity is due to a compound of oxygen and arsenic appearing as an ion. The most important oxides are As_2O_3 , or As_4O_6 called arsenious anhydride commonly known as 'white arsenic' and As_2O_5 arsenic anhydride.

Arsenic and arsenious compounds. In *arsenic* compounds arsenic is pentavalent, and in *arsenious* it is trivalent. Trivalent arsenic (arsenites) is generally much more toxic for protozoa, bacteria and yeast cells than is pentavalent arsenic (arsenates). The pharmacological action of arsenic is said to be due to the negative ion AsO_3 of arsenious acid H_3AsO_3 , in which arsenic acts as a trivalent element. It is held that compounds in which arsenic is pentavalent, i.e., derivatives of arsenic acid H_3AsO_4 , are reduced to arsenious compounds in the tissues. Though when given by the mouth there is no very marked difference in the toxicity of pentavalent and trivalent compounds, when introduced by cataphoresis (nodal diffusion) the arsenates are much less caustic to the tissues than arsenites. This difference is also borne out by toxicity experiments on guinea-pigs when the arsenites are found to be much more lethal than the arsenates. The ratio of toxicity of arsenious to arsenic acids when given intravenously to rabbits is 6 to 1 and for the excised frog's heart 800 to 1.

Organic compounds of arsenic. The organic compounds in which arsenic is combined with carbon behave somewhat differently from the inorganic compounds. As long as they are present in an unchanged condition in the body, they do not exhibit the ordinary action of arsenic. This is because arsenic is present in a non-ionic condition. During the process of oxidation and reduction in the body, ionic arsenic is gradually split off and the action of arsenic is produced. For this reason the action is delayed and is mild. Both trivalent and pentavalent arsenic can be readily introduced into a large variety of organic molecules. The decomposition of organic arsenicals is, as a rule, slow and passes through many intermediate stages of simpler organic

molecules; a considerable portion is in all probability excreted from the body in organic form during this process. The organic compounds are much more toxic to pathogenic protozoa infesting the animal body and that is the reason why they are largely used in the treatment of diseases produced by these parasites. When these compounds are tested, *in vitro*, they produce little or no toxic effect on the parasites and they therefore require the co-operation of the tissues of the host to become effective.

Jackson and Smith (1918) studied the action of these compounds on the circulation. The pulmonary pressure was enormously increased after intravenous injection of arsphenamine probably due to the obstruction of the pulmonary circulation caused by the alkalinity of the solution and possibly also to the presence of an embolic precipitate formed in the vessels. The specific action of the drug on the musculature of the arterioles may be another factor concerned. The effects produced by neoarsphenamine are not so marked as, owing to its neutral reaction, intravascular agglutination of erythrocytes and precipitates are less likely to be formed.

Rolleston (1915) observed the effects of intravenous injections of salvarsan and neo-salvarsan on patients; the general effect of the injection was rather to lower, certainly not to increase, the arterial blood pressure.

Absorption and fate of the organic arsenic compounds. The rate of absorption varies with the different modes of administration of these compounds. After intramuscular injection, neoarsphenamine, which is less irritating than arsphenamine, is more quickly absorbed. Swift found that after intramuscular injection of arsphenamine in rabbits, some 30 to 40 per cent. of the arsenic was absorbed during the first week, about 50 per cent. by the end of the second week, while at the end of 6 weeks about 80 per cent. had disappeared from the muscles. In the case of neoarsphenamine, 80 per cent. of the arsenic had been absorbed during the first week and 90 per cent. by the end of the second, while only about 5 per cent. remained in the tissues at the end of six weeks. Arsphenamine or neoarsphenamine when given intravenously leaves the blood stream rapidly, at least three-fourths disappearing in a few minutes. Observations in animals show that after a single injection of one of the organic arsenicals, the arsenic is found most abundantly in the organs whose capillaries would mechanically absorb the flocculates. These organs are the liver, spleen and the lungs, the size of the former making it the principal storehouse of arsenic. The liver gets rid of arsenic by excreting it in the bile, where its concentration is forty times higher than in the blood; of all the tissues the bones retain arsenic the longest. The brain, spinal cord and the

nerves contain traces and in the cerebro-spinal fluid also it can be detected after intravenous injections.

Some authors have laid stress on the arsenic stored in the body forming 'depots' from which therapeutically active substances are being constantly produced. Kolmer has shown that arsenic stored in the liver after repeated injections of arsphenamine and neoarsphenamine is not therapeutically active. The stored arsenic may produce injurious effects; it is known that arsenoxide is toxic to the tissues, but tissues can oxidise it to non-toxic products. The therapeutically inactive pentavalent arsenic may be injurious to tissues, and anything which hinders its excretion increases its toxicity without enhancing its therapeutic effects.

Excretion of organic arsenicals. *Pentavalent compounds.* After a single dose of these compounds, the arsenic is excreted promptly, and mostly in the urine. With continued administration, the excretion is prolonged, the greater part leaving within 3 days, but traces continue for 3 weeks; the effect is cumulative. A small part is excreted by the faeces. A large part of the arsenilate remains unchanged in the blood and tissues. The excretion of atoxyl commences early; as about 85 per cent. of the dose injected is excreted in the urine within 24 hours. The reason for this rapid excretion is that pentavalent arsenic is not fixed in the body cells. The inorganic arsenates are rapidly reduced in the body to the trivalent arsenites and in this form the arsenic is fixed in the tissue, but compounds, *e.g.*, atoxyl and tryparsamide, are reduced much more slowly and are therefore rapidly excreted by the kidneys.

Trivalent compounds. Salvarsan is excreted very slowly, the maximum amount of arsenic occurring in the urine being about 1.0 per cent. in 24 hours and a somewhat larger amount occurs in the faeces, the total amounting to about 3 per cent. The drug is excreted more slowly after intramuscular than after intravenous injections. Salvarsan is insoluble in neutral media and therefore cannot exist in the blood in true solution, but probably as a colloidal suspension. About 80 per cent. leaves the blood in five minutes after an intravenous injection, but small quantities circulate in the blood unchanged for 12 hours, and traces of arsenic can be detected in the blood for 12 days. The greater portion of the drug is fixed in the liver, where it forms a depot, from which it is released slowly. Neo-salvarsan disappears from the blood slightly more rapidly than salvarsan and is said to be excreted more rapidly.

It has been pointed out that during their excretion inorganic arsenic compounds set up cloudy swelling of the epithelial cells, fatty degeneration and hyperaemia of the sub-mucosa of the gastro-intestinal tract; the kidneys are affected in the same way. Organic arsenicals produce the same changes though not to such a marked extent. Arsenic is also eliminated by the skin; it is known to have a marked affinity

for the epithelial cells and it is probable that the production of ex-foliative dermatitis can be accounted for in this way and the presence of peripheral neuritis may further facilitate its production. In cases of organic arsenicals also, traces of arsenic are excreted in the saliva and milk.

It will thus be seen that probably only a portion of arsenic, in whatever way it is administered—by the mouth, subcutaneously, intramuscularly or intravenously—can exert therapeutic effects.

Classes of organic arsenic compounds. The starting point of all these are two acids, known as arsinic acid (trivalent) and arsonic acid (pentavalent). Arsinic acid is a dialkyl or diaryl derivative of arsenic acid, *e.g.*, cacodylic acid or dimethyl arsinic acid $(\text{CH}_3)_2\text{AsO.OH}$, or diphenyl arsinic acid $(\text{C}_6\text{H}_5)_2\text{AsO.OH}$. Arsonic acid indicates arsenic acid $\text{AsO}(\text{OH})_3$ in which one hydroxyl is replaced by an organic radicle. An arsonate is a salt of this acid.

(A) *Aliphatic (or fatty) series.* The effects of cacodylic acid are essentially those of the inorganic arsenic, to which it is partly reduced in the body. Sodium cacodylate is probably such a stable compound that it is broken down in the tissues to a very small extent. Very large doses can be given without producing any therapeutic, much less any toxic effect; it is excreted in the urine mostly unchanged but small quantities may be oxidised. Sodium cacodylate can also be given intravenously.

Calcium cacodylate, iron cacodylate, guaiacol cacodylate, magnesium cacodylate and strychnine cacodylate are some of the other compounds used either by the mouth or intramuscularly. They have been given in tuberculosis, diabetes mellitus, pernicious anaemia, exophthalmic goitre, leprosy, malaria, chorea, skin affections such as psoriasis and also in syphilis with varying results.

(B) *Aromatic (Benzol) series.* The development of this series of compounds is due to the efforts of Paul Ehrlich to obtain drugs which would destroy the organisms producing disease in the body. Clinical experience has already shown that protozoal infections, malaria, syphilis and amoebiasis may yield to specific drugs like quinine, mercury and ipecacuanha respectively, whilst no bacterial infection of man has been suppressed *in vivo* by chemicals. Evidently bacteria are more resistant, so that protozoa offer the more promising approach.

The starting point of Ehrlich's investigation was atoxyl which is the sodium salt of p-aminophenyl arsonic acid also known as arsanilic acid. His efforts were directed towards separating the antiparasitic portion from the toxic portion of the molecule. By multiplicity of changes, synthesis and experiments on thousands of infected animals, he endeavoured to find which atoms or groups of atoms and what grouping in the molecule increased the affinity for the parasites and reduced the toxicity to the cells of the host most. Substitutions

in the NH_2 group may cause profound differences in the effects of the compounds—sometimes an increase and sometimes a decrease in the therapeutic effect. If acetamide is introduced into the NH_2 group, tryparsamide is formed which is ten times less toxic than arsanilic acid.

A compound, sodium acetyl-p-aminophenylarsonate, also known as arsacetin or acetylatoxyl was prepared and this was followed by a number of other compounds. While these combinations proved useful in syphilis and in protozoal diseases they were not devoid of their toxic effects on the host. Ehrlich, from his experiments, concluded that these pentavalent arsenic compounds such as atoxyl and its derivatives, were really inactive in themselves and only acquired activity when they were changed into trivalent arsenic. This led him to seek for organic compounds in which arsenic was present in trivalent form. Many of these compounds were prepared of which arsenoxide, arsenophenyl glycine, etc., are examples, and eventually salvarsan and neo-salvarsan were discovered. These are very active compounds but during the last decade some powerful pentavalent compounds have also been prepared.

The aromatic compounds of arsenic may be divided into :—

(a) *Those in which arsenic is pentavalent. Arsanilic acid derivatives :*

Atoxyl is the monosodium salt of p-aminophenyl arsonic acid or p-arsanilic acid. It is also known as *arsamin* or *soamin*.

Arsacetin or sodium acetyl-p-aminophenylarsonate is tolerated in three to ten times as large doses as atoxyl. Its curative action against diseases caused by trypanosomes and spirochaetes is not marked.

Carbarsone or 4-carbamino-phenyl arsonic acid was first prepared by Ehrlich in 1909, but has only been recently used in the treatment of amoebic dysentery.

Since the war the study of pentavalent compounds has been keenly pursued. *Tryparsamide* (sodium-n-phenyl-glycinamide-p-arsonate) was discovered at the Rockefeller Institute, New York. Fournneau and his colleagues at the Pasteur Institute, Paris, produced a series of compounds of which *Fournneau 270* (Sodium-4-acetyl-amino-2-hydroxyphenylarsonate) and *Stovarsol* (Sodium-8-acetyl-amino-4-oxyphenyl arsonate) are well known. *Acetylarsan* is a simple derivative of stovarsol. They threw light on the relationship between chemical constitution and trypanocidal action. *Treparsol* or 3-formyl-amino-4-hydroxyphenyl arsonic acid is another compound which behaves like stovarsol. Both these compounds can be given by the mouth.

Etharsanol or monosodium salt of p- β -hydroxyethyl-amino-phenylarsonic acid and *Proparsanol* or monosodium salt of p- γ -hydroxypropyl-amino-phenylarsonic acid contain about 20 per cent. of arsenic. *Etharsanol* is an effective trypanocide experimentally and is on trial in man.

(b) *Those in which arsenic is trivalent.* *Arseno-benzene derivatives*:—These compounds are said to have a di-benzol or arseno-benzene nucleus coupled together by two trivalent atoms of arsenic. The nucleus itself is of no therapeutic value and is of interest only because it is the parent substance of salvarsan and neo-salvarsan (arsphenamine, neoarsphenamine, etc., in the United States).

Various substances were prepared by reduction of arsenic acid. *Arsenoxide* or 3-amino-4-hydroxy-phenyl-arsenic oxide is a toxic compound, its minimum lethal dose for white rats being 21.8 mgm. per kilo. body weight; *arsenophenyl-p-glycine* in the form of its disodium salt has a minimum lethal dose of 197 mgm per kilo. for white rats. This compound was called 'spirarsen,' 'spirarsyl' or No. 418 of Ehrlich's series and has got trypanocidal and spirochaeticidal properties in doses much smaller than its M.L.D.

Salvarsan is No. 606 of Ehrlich's series; it is the dihydrochloride of dioxy-diamino-arseno-benzene. It is also known as *arsphenamine*, *kharsivan*, *arsenobenzol*, *arsenobillon*, etc. *Arsphenamine diglucoside* is known as *stabilarsan*.

Neo-salvarsan is No. 914 of Ehrlich's series and is a condensation product of salvarsan. It is sodium-3:3'-diamino-4:4'-dihydroxyarseno-benzene methylene sulphonylate and is derived from salvarsan by introduction of a methylene sulphonic group into one of the amino groups. It is known as *neokharsivan*, *neoarsphenamine*, *novarsenobenzol* and *novarsenobillon*.

Silver sodium salvarsan and *silver neo-salvarsan* have a high chemotherapeutic index. The maximum tolerated dose for silver salvarsan is 167 mgm. and for silver neo-salvarsan is 278 mgm. per kilo. as compared with 870 mgm. of neo-salvarsan.

Metarseno argenticum is a compound of silver with metarsenobillon, (formaldehyde bisulphate derivative of arseno-benzene). Recently, compounds of salvarsan with bismuth have been introduced.

Sulpharsenol or sulpharsphenamine is disodium dihydroxy-diamino-arsenobenzene-*n*-dimethylene-sulphonate. It is also known as *sulpharsenobenzene*, *kharsulphan*, *myosalvarsan*.

Galyl (No. 1116 of Mouneyrat's series) is Tetraoxy-diphosphamino-diarsenobenzene and more recently *neo-galyl* which is the sodium salt of galyl has been prepared.

Ludyi (No. 1151 of Mouneyrat's series) is Phenyldisulphamino-tetraoxy-diamino-diarsenobenzene.

Luargol is 3:3'-diamino-4:4'-dihydroxy arseno-benzene-silver bromide-antimonyl-sulphate. A number of other co-ordination compounds with gold, mercury, copper and antimony have been prepared but they appear to have no superior therapeutic properties.

CHAPTER XXVIII

THERAPEUTIC USES OF ARSENICALS

Arsenious oxide has been used as an application in malignant diseases, its action being of slow caustic nature. Owing to the depressing action of arsenic on the nerves, it has been used in neuralgias, especially of the periodic type and in chorea. In rheumatism and asthma also it has been used and its administration in chronic skin diseases such as psoriasis, pemphigus, lichen and leprosy is well known. Here it probably acts by improving the nutrition of the skin. Arsenicals have also been used in infections with anthrax, *B. coli*, streptococcus and staphylococcus, with encouraging results. In puerperal septicaemia, erysipelas, pulmonary gangrene, gonorrhoeal arthritis, leprosy, broncho-spirochaetosis, typhus fever, and cancrum oris, they have been tried with encouraging results. The bactericidal properties of arsphenamine and neo-arsphenamine on the organisms of anthrax, glanders and swine erysipelas have been the subject of many papers. When injected into animals and the human body, arsenicals confer on the blood peculiar bactericidal properties which are retained for a considerable time. This will be seen from the fact that the serum of patients after injection of arsenicals exerts a bactericidal effect upon staphylococci and haemolytic streptococci. The arsphenamines, especially silver arsphenamine, have a toxic action on the leucocytes, but they have considerably stronger affinity for certain microbes, such as pneumococci and haemolytic streptococci than for leucocytes. In such infections sulpharsphenamine is now preferred in 0.3 gm. doses. The following scheme is usually followed: first two doses at an interval of 6 hours; 3rd dose after 18 hours; 4th after 24 hours; 5th after 48 hours; 6th after 3 days, 7th after 4 days and 8th after 5 days.

Anaemia. Bramwell (1875) first announced that arsenic was beneficial in the anaemia of the pernicious type. Since then Fowler's solution and other preparations of arsenic have been

very largely employed in this disease and also in such conditions as leukaemia. Unfortunately the improvement produced is of a very temporary nature. In other anaemias arsenicals are said to act (1) by destroying the parasitic agent responsible for producing the condition, (2) by stimulating the bone-marrow and other blood-forming tissues, (3) by increasing the resistance of erythrocytes against hæmolytic agents, (4) by generally improving the metabolism. Excellent effects are produced by arsenicals in anaemia of syphilitic origin. Kolmer (1925) observed that arsphenamine and its substitutes cannot be regarded as curative agents, in a strict sense, for the non-syphilitic anaemias. They however improve the condition and small doses of neo-arsphenamine (0.1 to 0.3 gm.) give better results than inorganic arsenic by the mouth.

Helminthiasis. (See Part II, Helminthic Diseases). Arsenicals have been tried against some of the helminthic infections such as bilharziasis but have not proved very successful. McNerthney (1916) and Nieto (1924) recorded apparently successful results with 2 or 3 intravenous injections of neo-salvarsan in doses of 0.45 gm. each against trichinosis.

Some of the trivalent organic arsenicals are said to have a filaricidal effect, but this is doubtful. They do sometimes cause disappearance of microfilariae from the blood and chyluria is often benefited by tryparsamide. Neo-salvarsan has been used in the treatment of guinea worm.

Malaria. Inorganic compounds of arsenic such as arsenious oxide or arsenites have been used to reinforce the action of quinine in malaria, especially in those cases in which cachexia is present. Some authorities consider arsenicals to be of value in acute cases of the disease and they are supposed to act (1) by destroying the parasites which have a low susceptibility to quinine and (2) by increasing the vitality of the tissues generally, and particularly of those concerned in the formation of blood. They are said to cause disappearance of the parasites of benign tertian type though they have no effect on the subtertian parasites. This also does not appear to be the case, but there is no doubt that arsenic compounds do help the action of quinine.

The organic arsenicals on account of their trypanocidal and spirochaeticidal properties were tried in the treatment of malarial fevers, and it was shown that injections of salvarsan and neo-salvarsan may stimulate cases of chronic malaria into activity, sometimes with fatal results. In some cases this reaction has been used as a provocative method for finding the parasites in the blood. This dislodging of the parasites is probably caused by the vasodilating action of these compounds. Some authorities lay stress on the arsenicals being useful adjuvants to quinine, especially in chronic quartan and tertian infections, while others say that they may be actually harmful. In malaria of birds, arsenicals have no effect and tend to lower the resistance of these animals. Stovarsol in 1.0 gm. doses by the mouth several times a day is said to be efficacious in malaria.

Clinical experience shows that organic arsenicals such as salvarsan, neo-salvarsan, and stovarsol possess only slight parasito-tropic properties against the plasmodia of malarial fevers of man; they have little or no effect on the sexual forms. In acute malaria they cannot be recommended. In chronic malaria the arsenicals tend to bring the parasites into the blood where they are exposed to the action of quinine. Further, they improve the anaemia and generally stimulate the metabolism and nutrition. Injections of soamin are often useful.

Trypanosomiasis. Bruce (1895) first used the arsenical preparations in the treatment of the trypanosome infections of animals 'nagana' and 'surra.' Ehrlich and Shiga (1904) studied the effects of atoxyl and other substances on trypanosomes *in vitro* and Thomas (1905) showed that atoxyl cured laboratory animals infected with a number of different species of trypanosomes. Koch (1907) employed atoxyl in the treatment of sleeping sickness in Africa and although the first results were good, relapses occurred and optic atrophy was often produced. Tryparsamide and Fournieu 270 were introduced after the War and this was a further step in the treatment of this disease but the hope that the disease could be eradicated has not been realised.

Attempts to get compounds which may have trypanocidal activity, when given by the mouth, have also not been successful. No compound

has been discovered which will penetrate the central nervous system to a greater degree than tryparsamide. Etharsanol (p- β -hydroxyethyl-aminophenylarsinic acid) and Proparsanol (p- γ -hydroxy-propylamino-phenylarsinic acid) differ little in their chemical composition from tryparsamide. The former contains 20.32 per cent. of arsenic and is toxic, but the latter has 20.68 per cent. of arsenic and has a similar action to tryparsamide. Etharsanol given intravenously is very rapidly excreted and therefore can be given in maximum tolerated doses. In man 15 per cent. was excreted in 5 hours, and 91 per cent. in 4½ days. In rats and rabbits infected with *T. brucei*, *T. equiperdum*, *T. equinum*, *T. lewisi*, and *T. rhodesiense*, etharsanol is an effective drug. Rabbits could even be cured when, as shown by lethargy and paralysis, the central nervous system was affected; on analysis, brain substance was found to contain large quantities of arsenic. The drug has so far been tried only in a few human cases.

A number of other arsenic acid derivatives have been tested on mice infected with *T. equiperdum*. Some of these compounds resemble stovarsol in action while others resemble tryparsamide. Some of the benzisoxazinearsinic acid derivatives are just as effective in animals when given by the mouth as when given by injection. Some of these compounds have been tested in human trypanosomiasis, but they produce diarrhoea and vomiting without any amelioration of symptoms. Stovarsol by the mouth is ineffective. A large number of derivatives of phenylarsinic acid have also been tested. Acetylarsan in doses of 0.75 gm. each, given subcutaneously at intervals of one week till 12 gm. are given, improved the general condition and produced a decrease in the lymphocytosis in the cerebro-spinal fluid. The results were inferior to tryparsamide. Fourneau 269 and 417 have also been tried with variable results.

The trivalent compounds of arsenic are not so effective in this condition. The pentavalent compounds act more efficiently on the parasites in the blood and cause their prompt disappearance, but have comparatively less effect on those which have infected the lymphatic glands and apparently they do not penetrate in sufficient concentrations to destroy the organisms present in the central nervous system. The supply of the parasites into the blood stream is, therefore, constantly renewed from these foci; but there is no doubt that they ameliorate symptoms and prolong life.

Jamot (1926) treated 50,000 patients with atoxyl, and found that treatment of the population with atoxyl on a large scale failed to eradicate the disease. He also tried tryparsa-

mide and testified to the beneficial effects produced by this drug in advanced cases of the disease. In the early stages when the cerebrospinal fluid is not infected with the parasites, atoxyl, which is cheaper, should be prescribed. It is given in doses of 1.0 to 1.25 gm. to adults, the doses being given at intervals of 10 to 16 days, a series of six injections constituting a course. In the second stage moderate doses produced slight clinical amelioration, but the effects were of short duration and after 4 or 5 months the patients had relapses. In advanced stages of the disease when the cerebrospinal fluid contains leucocytes and albumin, tryparsamide is recommended. Whenever there is doubt about the stage and when lumbar puncture cannot be done, tryparsamide which gives better results in both stages should be tried.

Dengue. This disease is sporadic in many parts of India but has occasional epidemic exacerbations. The disease is carried by some species of mosquito, *Culex fatigans* in Syria and *Stegomyia fasciata* (*Aedes ægypti*) in Australia and other countries. Clinically it resembles phlebotomus fever; the blood of early cases of both phlebotomus fever and dengue is infective if inoculated in susceptible persons even after passage through a Berkefeld filter, indicating an ultra-microscopic stage of the causative organism. The disease can also be transmitted to guinea-pigs. Spirochaetes are probably not the causal organisms. Novoarsenobenzol in 0.45 gm. doses has been tried in this condition but has little effect. Pirot (1927) treated 17 cases of dengue with intramuscular injections of 6 gm. of sulpharsphenamin on the first three days of the disease. In nine cases there was a marked lowering of the temperature and decided amelioration of the joint and bone pains. Relapse was also prevented in the other eight, the fever was of shorter duration than in the controls, and although there were relapses, they were not as severe as in the untreated cases. Treparsol has been tried by the mouth in 15 grain doses (1.0 gm.) per diem for the first 3 days. Although the disease was not cut short there was amelioration of symptoms. The best results were obtained by hypodermic injection of 3 c.cm. of acetylarsan. If given about the second or third day it is said to abort the fever.

Intestinal protozoal and other infections. Musgrave (1922) has shown that chronic diarrhoea with intermittent exacerbations and other digestive disturbances occur in infection with *Giardia intestinalis* and trench-diarrhoea so common during the Great War was also attributed to this organism. In children, lamblasis is said to produce wasting, retardation of growth, etc. Salvarsan, neo-salvarsan and stovarsol by the mouth have offered more encouragement in the treatment of this condition than any other drug. It has been shown that after an intravenous injection of neo-salvarsan, arsenic appears in the duodenal fluid in $1\frac{1}{2}$ hours but the flagellates remain at first active. The arsenic reaction is increased after about 2 hours and the flagellates become motionless. Later, arsenic reaction is absent but flagellates disappear altogether. Stovarsol in doses of 0.5 gm. per day by the mouth has been used in chronic amœbiasis and in the treatment of lamblia as well as trichomonas infestations. *E. coli* and *E. nana* are said to disappear from the stools rapidly. Carbarsone has recently come into use in amœbiasis and is stated to be less toxic than stovarsol.

Diseases produced by spirochætes or spirilla or spironema.
Relapsing fever. This disease is met with in Eastern Europe and North Africa, India and the Southern United States. *Sp. duttoni* is the causal organism in the Central African variety which is practically the same organism as *Sp. recurrentis*. This infection is transmitted by the tick *Ornithodoros moubata*. Monkeys can be readily infected and lice are the carriers of infection in man. The fever varies much in severity, the first attack usually lasts six days, and relapse occurs after seven or more days, intermissions being few in number. An enormous mortality occurred in Russia during the War and in subsequent famines. Localised outbreaks occur in different parts of India during April and May. *Spironema berberium* in Persia is probably transmitted by the bite of the tick *O. tholozani* or *miana*. The ticks or lice become infected by biting the patients suffering from the disease. The spironema become granular in their stomachs in three hours and disappear in twenty-four hours and after 10 days appear in their hæmolymph in which they persist. The fluid which escapes from the louse

after crushing is highly infective. Infections with spirochaetes occur in squirrels in China and India.

In the early work of Hata and Ehrlich on the organic arsenicals, mice infected with *Sp. obermeieri* were used. The inorganic compounds have little or no effect on this spirochaete infection and even the organic compounds have a less powerful effect on these organisms than on the trypanosomes. Recent experiments with mice infected with the spirochaetes of relapsing fever show that injections of salvarsan cause a rapid disappearance of the organisms from the blood but they still persist in the brain. Though a single injection may bring about an apparent cure, the spirochaetes may still remain active in the central nervous system. Strains of relapsing fever spirochaetes differ in their resistance to arsenic. Clinically, encouraging results have been obtained in the treatment of relapsing fever, 0.2 to 0.3 gm. of arseno-benzol compound producing a sudden fall of temperature in a few hours; spirochaetes disappear from the blood and the patient appears to be cured. The fall of temperature is accompanied by rigors, which are said to be produced by the liberation of endotoxins from the parasites killed by the drug. Full and repeated doses have to be given before the parasites can be eradicated from the brain. Neo-salvarsan in doses of 0.45 to 0.6 gm. produces excellent results in relapsing fever. As a routine 7 to 8 doses are necessary, one being given every week, and cases treated at the commencement of the illness respond much more quickly than patients who have had relapses. One and a half gm. of stovarsol given by the mouth on two successive days is said to produce disappearance of the spirochaetes from the blood in 6 to 36 hours and to prevent relapses. The drug has also been used prophylactically.

Rat-bite fever. Rat-bite fever is caused by *Spirillum minus* which is a spirillum of rigid structure conveyed to man by the bites of rats, cats and weasels which are infected with the parasites of the disease. The infection is characterised by an acute febrile reaction with a local disturbance at the site of infection and in some cases cutaneous eruptions. The organisms appear in the blood stream usually seven days after inoculation and persist for several months afterwards. The incubation period

of the disease is 5 to 10 days or more. Fever comes on with rigor and malaise and ends by crisis about the sixth or seventh day. Relapses frequently occur. One or two injections of neo-salvarsan suffice to bring down the temperature and cause disappearance of the roseolar rash. The injections should be given early in the course of each spell of fever rather than at the end of the paroxysm or in the fever-free period. In severe cases 0.6 gm. to 0.9 gm. at weekly intervals for about 6 weeks is necessary. Oxy-acetyl-amino-phenyl arsinic acid has been tried in rabbits infected with rat-bite fever. The prophylactic use of arsenic has also been found successful.

Syphilis. This disease is produced by *Spirochaeta pallida* now more correctly called *Treponema pallidum*. It is acquired by contact, commonly sexual intercourse or is transmitted through the mother. The name 'syphilis' first appeared in 1530 in a poem, 'Syphilus' being the name of the infected hero. It is essentially a parasite of the lymphatic system and tissues. The organism is extracellular in the body and occurs practically in all the tissues particularly the cardiovascular, lymphatic and nervous tissues. The introduction of organic arsenical compounds marked a new era in the treatment of syphilis. They produce most remarkable results on the lesions produced by the disease and the dictum 'once a syphilitic always a syphilitic' is gradually giving way to the belief that the disease is curable. It is probably one of the transformation products which destroys the parasites and prevents the development of new generations, for *in vitro* their action is not very powerful, and the effect is enhanced by adding an extract of liver. It was hoped at first that a single injection would suffice to destroy all spirochaetes and realise the ideal of '*therapia sterilisans magna*' but though this hope has not been entirely fulfilled, very often a single dose causes disappearance of spirochaetes and the Wassermann reaction becomes negative; but in a large majority of cases spirochaetes reappear and the symptoms develop again. This is due to the fact that the first injection suffices to kill a large number of parasites, but a few which survive reinfect the tissues and develop a certain degree of tolerance to the drug. The drug should be injected repeated-

ly at regular intervals while vigorous mercurial treatment at the same time is recommended. Injections should be started as soon as the diagnosis is confirmed and before the parasites have had time to reach inaccessible positions in the tissues. Within two weeks of the initial lesion it may, if given in repeated doses, produce a complete cure. In patients with primary and secondary manifestations like ulceration of the penis, mucous patches in the mouth and throat, arsenicals have a marvellous effect in clearing up the lesions. Their power to produce a perfect cure diminishes as each week passes, and after secondary symptoms have appeared, the question of cure in the true sense becomes problematical. One of the important results of treatment is that the patient becomes relatively innocuous as far as transmitting the disease to others is concerned. The arsenicals also shorten the contagious period of the disease and afford a sure protection against the development of tertiary and quarternary manifestations. It should be borne in mind that these compounds should be given in adequate doses ; too small doses not only fail to cure but are believed to produce a resistant strain of spirochætes. Stovarsol by the mouth is said to be effective against syphilis but this needs further confirmation.

Syphilis of the central nervous system. There has been considerable difference of opinion regarding the presence of arsenic in the cerebro-spinal fluid after injections of the arsenicals. The exact origin of this fluid is not known, but it is probably a form of secretion of the choroid plexus and ependymal cells which effectually prevent the passage of most drugs into it. Hexamine, chloroform, etc., may pass into it, but from the point of view of drugs used in the treatment of syphilis, mercury has never been found in this fluid and iodine has not even been detected after intravenous injection of iodides. It is probable that in disease of the meninges these substances may pass into the cerebrospinal fluid.

Lately much work has been done to determine the penetrability of organic preparations of arsenic into the cerebrospinal fluid. The experiments consisted of both quantitative estimation by chemical methods as well as biological methods in

which the effect on *T. brucei* present in the central nervous system was determined. The conclusions are as follows:—The penetration of arsenic into the cerebro-spinal fluid following intravenous injections of arsephenamine, neoarsphenamine, silver arsphenamine, etc., is very small and these drugs have a relatively low effectiveness in cerebral affections.

Sulpharsphenamine or sulfarsenol is said to be the most effective of the arseno-benzene derivatives in this respect and possesses superior therapeutic power in syphilis of the central nervous system to any of the other arsenicals. Greater therapeutic effect can be produced by giving large doses of arsenicals at longer intervals. Tryparsamide has also been recommended in the treatment of neuro-syphilis and often the patients show signs of distinct clinical improvement. Eight consecutive weekly injections are recommended in a course, which may be repeated at suitable intervals.

Arsenicals differ from mercury in the greater rapidity of their action. This is due to the fact that sterilising concentration of mercury can be reached only after several days, while given by the intravenous route salvarsan acts in a few hours. The disadvantage of the arsenicals is that most of them are excreted within 3 days and the surviving parasites multiply unrestrained. A combination of the two therefore appears to be the best; the arsenicals have supplemented rather than replaced the older drug. A number of organic compounds containing both arsenic and mercury were introduced but they proved to be disappointing. A course of iodides at various stages of the treatment is decidedly helpful. Probably it acts by breaking down the fibrous tissue which surrounds the spirochaetes in the lesions.

Frambæsia. Yaws is one of the most widespread tropical diseases. It is prevalent in Africa and Asia. In India it occurs in Assam and parts of Bihar, in Ceylon and Burma. The causal organism is *Treponema pertenue* which is indistinguishable morphologically from *T. pallidum*. Serum reactions like the Wassermann test and Sachs-Georgi reaction are also positive in yaws. Rabbits can be experimentally infected with the organisms of yaws. *T. pertenue* is not as

virulent as *T. pallida* and hence experimental yaws is more readily influenced by arsenicals than syphilitic infections.

Nichols (1911) was the first to discover the curative effect of salvarsan in yaws in rabbits. Clinically the arsenical compounds produce a wonderful effect in yaws in man. The prompt effect produced by a single injection is such that it is often difficult to get the patients to realise the necessity for continuing the treatment to ensure permanent effects. After two or three injections the long-standing lesions disappear and the patient is usually cured. Stovarsol by the mouth in 0.5 to 1.0 gm. doses for 7 to 10 days has been used with good results. Treparsol has also been used orally with good results; 4.25 to 14.75 gm. are necessary to produce a cure. In Western Samoa, where yaws is very prevalent, the standard treatment followed is to administer three doses of a trivalent compound intravenously at one week's interval.

Although the introduction of arsphenamine has revolutionised the treatment of yaws, real cure is not always attained. The secondary eruptions undoubtedly disappear, but many cases pass into a latent condition. A course of six injections of 0.6 to 0.75 gm. of neoarsphenamine has been recommended at intervals of a week or ten days to prevent relapses. With three injections of 0.6 gm. there is a relapse rate of 10 per cent. within 8 months. The serum reaction remains positive in many cases. Intramuscular injections of sulpharsphenamine are effective, 2 to 3 injections being required. Some cases are resistant to the action of neoarsphenamine (see also bismuth).

Vincent's angina is generally regarded as being due to a spirochæte and the *Bacillus fusiformis*. Injections of arsphenamine are very useful in this condition. The influence of arsenicals on the saprophytic spirochætes of the mouth is very doubtful and the role of spirochætes in the production of bronchitis is highly uncertain. In cases of pulmonary gangrene associated with spirochætes in the lungs, excellent results have been obtained by injection of arsphenamine.

Other conditions. In cerebro-spinal fever, injections of arsenicals may produce improvement. Phagedenic ulcers of the mouth improve by painting with stovarsol solution. In veteri-

nary medicine they have assumed great importance and besides diseases of protozoal origin they are also used in the treatment of contagious diseases of the lungs especially in horses. Against anthrax and glanders they are also said to have a beneficial effect.

The action and therapeutic uses of some of the most important members of the group will now be discussed in detail.

MODES OF ADMINISTRATION

Local application. One in 1000 solution of salvarsan and neo-salvarsan exert spirochaeticidal effects on *T. pallidum* and *T. pertenue* in chancres, mucous patches and other syphilitic and framboesial ulcers; some of the other spirochaetal affections such as Vincent's angina are also benefited. Under the microscope, 1 in 1000 solution destroys the motility of the spirochaetes immediately. A one per cent. ointment of arsphenamine applied within an hour of exposure, or powders applied to ulcers, are effective in preventing infection; they do not produce irritation.

Oral and rectal administration. Salvarsan was first tried by Hata in a human case at the Imperial Institute of Tokyo. Oral administration was tried and although there were no toxic symptoms except vomiting and diarrhoea the therapeutic effects were very feeble. Kolmer (1912) and others have shown that arsphenamine is absorbed when given by the mouth but produces symptoms of gastro-intestinal irritation. To Rabaut belongs the credit of introducing arsenical compounds by the mouth in the treatment of amoebic dysentery and pentavalent compounds like stovarsol and treparsol are now sold in tablet form and are largely used with satisfactory results.

The rectal method has been tried with salvarsan but is even inferior to the oral route. After administration of 0.6 gm. per rectum, only traces were found in the blood while the urine gave a negative test for arsenic. Arsenobenzol suppositories containing 0.1 gm. each have been prepared and are used in the treatment of diabetes mellitus.

Subcutaneous and intramuscular injection. Subcutaneous and intramuscular injections have been tried in aqueous

solution, olive oil or liquid paraffin but salvarsan tends to deposit locally and gives rise to pain and swelling even when the solutions are carefully neutralised or mixed with olive oil (10 per cent.) before injection. The rate of absorption from the muscles depends primarily on the degree of injury to the tissues; neo-salvarsan, which is neutral in reaction, produces less irritation than salvarsan, which is acid, and is therefore absorbed 5 to 6 times more quickly. It has however been found locally for as long as 36 days or even later, and repeated injections may cause cumulative poisoning. Kolmer (1926) conducted experiments upon the rate of absorption of arsenicals and found that as compared with neo-arsphenamine in the same dose and concentration, the absorption of sulpharsphenamine was generally but not always considerably more rapid and likewise produced less tissue injury. It is the only one of the trivalent arsenicals which can be safely given by this route and produces the therapeutic effects desired. The advantages of the subcutaneous and intramuscular routes are that acute toxic reactions are much less common though they are not altogether eliminated; the disadvantages are that local reactions are produced. The pentavalent compounds such as atoxyl, tryparsamide, stovarsol, as a group produce less local reactions than trivalent compounds.

Intraspinal, intraperitoneal and intrapleural methods. Even when well diluted with spinal fluid, the arsenical compounds given in the spinal canal produce considerable irritation of the cord causing severe shooting pains; the respiratory and cardiac centres are not affected. This form of medication is as a rule not employed. The safest medicine for subdural injections is the serum of patients who have recently received injections of arsenicals. As intraperitoneal and intrapleural injections produce irritation they are not recommended.

The administration of most of these compounds by ordinary methods is not very effective in cerebro-spinal syphilis, as very little of the drug passes into the cerebro-spinal fluid. The plan of doing a lumbar puncture after injection so as to set up a negative pressure and an ultrafiltration through the choroid plexuses, has been recommended. This is absolutely harmless and said to produce beneficial effects.

Intravenous route. The intravenous method is the one usually adopted. The disadvantage of the intravenous method is that the drug is rapidly eliminated and consequently the period of spirochæticidal activity is short. Besides, the technique is more difficult and the incidence of acute toxic reactions is higher, due to factors inherent in the drug itself or in its solvents. The main advantage is the freedom from pain and disability when intravenous injections are properly given. The intravenous route is preferred in acute early stages of syphilis for rapid destruction of spirochætes in lymph, blood, and tissues; in later stages however when most of the organisms are fixed in the tissues, the intramuscular and subcutaneous routes are preferred by some, because the absorption and excretion rates are reduced and spirochæticidal effects are enhanced. Some give intravenous and intramuscular injections alternately. After intravenous injections the reticulo-endothelial cells of the spleen, liver and lymph glands become swollen, and granules of the compounds can actually be demonstrated in them. After very large doses of neo-salvarsan the granules can be demonstrated in the capillary endothelium, the intestine and the salivary glands as well.

The elaborate technique of preparation, neutralisation and injection of salvarsan is no longer necessary with neo-salvarsan and other allied compounds, as they have a neutral reaction when dissolved in distilled water. The temperature of the solution should not exceed 22°C. or 71°F. Slight febrile reaction generally occurs after the first injection; if this reaction reappears in the course of the treatment (*i.e.*, on subsequent injections) it is a sign of intolerance. The rate of injection of these compounds is of importance. A concentrated solution injected slowly is as well borne as a dilute solution injected rapidly; but if injected rapidly they both produce a higher incidence of toxic reactions. With solutions of neo-salvarsan, sulfarsenol and tryparsamide the importance of rapid injections is not so great as with those of salvarsan, as the former being neutral in reaction do not produce intravascular reactions such as hæmolysis, agglutination and precipitation. The kidneys should be

carefully watched and the urine tested for albumin before each injection. Sometimes the rubber tubing, through which solutions pass, may produce toxic symptoms; this is due to the inferior quality of rubber and boiling does not prevent such effects.

A study of the various vehicles for the injection of the novarseno-benzol compounds has been made. In order to get the quickest and best results in the treatment of syphilis, the tendency is to give these preparations in doses as large as possible and to shorten the interval between courses. This unfortunately often produces toxic and sometimes fatal results. In order to avoid angioneurotic symptoms, dermatitis and other complications, a number of diluents other than saline were tried. Blood serum, glucose, saccharose, calcium chloride, egg albumin, and gum, have all been tested. Neo-arsphenamine dissolved in 5 to 20 c.cm. of a 6 per cent. aqueous solution of caesium eosinate in place of distilled water is said to prevent anaphylactic symptoms. It is an expensive compound and if not pure it is toxic. Of all these, glucose appears to be the best as to some extent it prevents oxidation. Thirty c.cm. of a 30 per cent. solution of glucose, given intravenously in conjunction with neo-arsphenamine is said to increase the efficacy of the latter. Gelatine, blood serum and calcium chloride have proved effective in some cases.

CHAPTER XXIX

ORGANIC COMPOUNDS OF ARSENIC

ATOXYL

Synonyms :—Soamin, Sodium-p-arsanilate, Arsamin, Trypoxyl, Atoxylon.

It is a white odourless crystalline powder with a saline taste, soluble in 6 parts of water and 125 parts of alcohol. It contains 27.2 per cent. of arsenic. Under the misleading name of atoxyl (for the substance is quite toxic), it was extensively used at one time in trypanosomiasis (sleeping sickness), syphilis and other protozoal diseases. A number of compounds similar to atoxyl have been tried in trypanosomiasis. *Soamin* is practically identical with atoxyl, differing only in the amount of water of crystallisation. *Arsacetin* resembles atoxyl closely in its effects. Atoxyl on account of its property of getting decomposed in the gastro-intestinal tract is not given by the mouth but is usually given hypodermically or by intramuscular injections into the buttock in 10 per cent. solution. The dose is 0.02 to 0.2 gm. every other day. It is non-irritant, is absorbed rapidly and circulates in the blood longer than the arsenites and can therefore exert its parasiticial action for a much longer time than the latter group of drugs. Atoxyl deteriorates by storage ; its solutions should therefore always be freshly prepared and sterilised before use.

Atoxyl has no action on the trypanosomes *in vitro* and can only become effective when it undergoes certain changes in the body. Most of it passes through the body unchanged and the small portion which remains is changed into bodies which are capable of destroying the parasites. The active therapeutic agent is probably arsenic and the reason why atoxyl is superior to inorganic preparations is that owing to its solubility it can penetrate into the tissues more rapidly than the inorganic preparations. There has been some discussion as to how its specific action is produced in the body. Some believe that part of the atoxyl is split up in the tissues, giving rise to an inorganic arsenic which is the active agent, and there is no doubt that inorganic arsenic destroys the parasite both in the blood and *in vitro*. This arsenic may

be liberated in the bodies of the parasites into which atoxyl has penetrated. Ehrlich held that it is partially reduced in the tissues and that the product of reduction is an active trypanocidal body. This was the idea which led him to seek for active trypanocidal drugs in the reduction products of atoxyl. Experimentally, the reduction was effected by chemical agents like hydrochloric acid, sulphurous acid, etc., and the resultant products were tested for their trypanocidal properties *in vitro*. A long series of experiments on this line eventually led to the preparations of salvarsan and neosalvarsan. One of the reduction products of atoxyl is *p*-hydroxyphenyl arsenious acid which kills trypanosomes *in vitro* in high dilutions, while atoxyl has no toxic effect in 5 per cent. solutions. The enormous changes in toxicity produced by reduction are thus obvious.

Effects on animal trypanosomiasis. Thomas and Breinl (1905) found that atoxyl cures experimental trypanosomiasis in mice; Koch (1907) reported beneficial results in similar infections. Favourable results were also obtained in chicken spirillosis. Voegtlin and Smith (1920) showed that the maximum tolerated dose (M.T.D.) of anhydrous atoxyl is 239 mgm., the minimum lethal dose (M.L.D.) 358 mgm. and the minimum effective dose (M.E.D.) in experimental trypanosomiasis is 89.6 mgm. per kilo. body weight.

Therapeutic uses. Atoxyl was introduced in the treatment of trypanosomiasis many years ago and in spite of the many new preparations that have been introduced it still continues to hold its field. Unfortunately it does not eradicate the disease in all its stages. It acts efficiently on the parasites in the blood, but has less effect on those which have infected the lymph glands, and apparently it does not reach those present in the central nervous system in sufficient concentration to destroy them. On administration of this drug the parasites disappear from the blood, but the supply is being constantly renewed from foci in the lymphatic glands and in the nervous system. Although cases of complete cure are on record, in the majority of cases it only alleviates symptoms and may prolong life. Small doses, such as 0.5 to 0.75 gm. weekly in an adult gave poor results and failed to avert relapses; 0.015 to 0.02 gm. per kilo, or 1 to 1.25 gm. gave good results. Of 84 cases in the first stage of the disease treated in this way, only five relapsed in seven to sixteen months. In the second stage, moderate doses decreased the meningeal reaction, as shown by the degree of lymphocytosis and clinical amelioration, but the effects were

of short duration. Chesterman (1925) recommends 1 gm. doses weekly for ten to twelve weeks.

Atoxyl was also used in the treatment of syphilis but the frequency with which it causes optic atrophy and blindness precludes its use for prolonged treatment of any disease. Soamin has been used in the treatment of many obscure conditions by medical practitioners in India. Intramuscular injections of this drug are given in asthma, anæmia and debility, affections of the respiratory and gastro-intestinal tract, filariasis, chyluria, apparently with good results. The drug probably acts as a hæmopoietic and as a tonic, but it appears to have no specific action in these conditions. It is given in increasing doses up to 5 grains twice a week and sometimes 20 injections or more may be given. It should be remembered however that soamin is a toxic drug and should be used with caution.

Toxic effects. Those produced with doses exceeding 0.5 gm. resemble the acute symptoms occurring in ordinary arsenic poisoning; these are dryness of the throat, headache, fever, colic, vomiting and diarrhœa, nephritis and paralysis of the lower limbs. The most serious effects are disturbances of vision, and these as a rule only occur when large doses of the drug are given at short intervals. They begin with scintillation, cloudiness, dimness and contraction of the field of vision, especially on the nasal side, which may lead to total and permanent blindness. Loss of vision can be easily produced in animals and is due to degeneration of the ganglion cells of the retina and later, of the fibres of the optic nerve. Though the retina is particularly susceptible, the cerebral cells are not immune and are also injured. Ophthalmoscopic examination shows at first no changes save that the retinal arteries may be narrowed and the veins somewhat hyperæmic; later there is complete optic atrophy. Evidence has been produced to show that the most important factor in the production of optic lesions is the presence of the amino group in the para position to the arsenic.

TRYPARSAMIDE

Synonyms :—Moranyl, Sodium-n-phenyl-glycinamide-p-
arsonate.

This compound is a derivative of atoxyl which was synthesized and developed in the Rockefeller Institute. Tryponarsyl Meurice is a Belgian product having a similar chemical composition. Like atoxyl it is a pentavalent compound. It is a white, odourless, crystalline powder containing 24.6 per cent. of arsenic. It is very soluble in water forming a neutral solution which is comparatively stable, so that a 10 per cent. solution can be boiled without decomposition. Its toxicity is very low and it is only slightly irritant and can be given intramuscularly, intraperitoneally (in animals) and intravenously.

The M. L. D. for monkeys is 1.25 to 1.5 gm. intravenously; slightly larger doses are required by the intramuscular route. Symptoms of intoxication are nervous and nutritional disturbances such as occur with all pentavalent compounds. There are tremors, inco-ordination of movements, clonic spasms, weakness and prostration; the appetite is lost and animals are emaciated and occasionally suffer from diarrhoea. The pathological changes consist of vascular dilatation, congestion, scattered petechial hæmorrhages and degenerative changes in internal organs. The minimum therapeutic dose for mice infected with *T. brucei* was found to be 0.2 gm. per kilo. when given subcutaneously and intravenously, and 0.275 gm. when given intraperitoneally within 24 hours after infection. The chemotherapeutic index for mice was 1:8 while for rats infected with *T. evansi* it was 1:3. Rabbits, rats and mice infected with *T. gambiense* can be more readily treated than those with *T. rhodesiense*.

Table showing M. L. D. of tryparsamide in animals in gm. per kilo. of body weight (Findlay, 1930).

Animal		Methods of Administration		
		Subcutaneous	Intravenous	Intraperitoneal
Mouse	...	2.75	2.0	2.0 to 2.25
Rat	...	1.0	.	0.75
Rabbit	...	1.10	0.75 to 0.90	1.10
Guinea-pig	...	1.50	...	1.50

Its trypanocidal activity *in vitro* is feeble as the organisms remain motile in 1 in 100 solution. In mice injected with *T. brucei* the trypanosomes rapidly disappear, the ratio between curative and lethal dose being 1 to 10 as compared with 1 to 4 of atoxyl. Amphoteric arsenical compounds, *i.e.*, those containing both basic and acidic groups, are said to be more frequently trypanocidal than the non-amphoteric.

Dosage and method of administration. In adults the dose is 2 to 3 gm. and in children 0.5 to 1 gm. according to age. The drug has been tried in sleeping sickness in doses of 2 gm. intravenously (0.112 gm. per kilo. body weight). Solutions should be freshly prepared, 2 to 3 gm. being dissolved in 10 c.cm. of cold sterile water. Such solutions should be clear but it is advisable to filter them through sterile filter papers, any turbidity necessitating the rejection of the solution. Boiling should be avoided as it may produce decomposition and toxic compounds. The drug is well tolerated intramuscularly in 20 per cent. solution; 30 per cent. solutions produce more discomfort and may lead to abscess formation. It may be given by this route but usually the intravenous route is preferred. Subcutaneous injections are not recommended as they produce irritation and supuration. Ten weekly injections of 40 mgm. per kilo. body weight in a 10 per cent. solution are considered safe. The toxic effects of this drug are confined to doses close to the M. L. D. and the recovery of animals from sublethal intoxications is remarkably rapid and complete. This makes possible the repeated administration of very large doses of the drug at comparatively short intervals without incurring the danger of cumulative toxic action. By taking advantage of this peculiarity of action, it is possible to develop such a high degree of tolerance on the part of the animals that doses larger than the M. L. D. can be given. This is a very important feature of the toxicological action of tryparsamide which is of great significance in the use of the drug for therapeutic purposes.

Toxic effects. Untoward effects with this drug are not commonly met with. The most serious such as amblyopia, nitritoid reactions and exfoliative dermatitis have not been noticed and jaundice is a rare complication. As a rule 80 to

90 per cent. of the drug is excreted during the first 24 hours after injection, but in certain individuals it is excreted slowly and they are more susceptible to the cumulative effects of the drug.

The untoward effects generally appear after the fifth or sixth injection, the symptoms consisting of a sensation of dazzling; on examination the fundus is found to be hyperæmic; the visual fields are contracted on the nasal side. In severe cases contraction goes on till complete blindness results. Involvement of the optic nerve is by no means rare in neurosyphilis. All such cases should therefore be thoroughly examined by an ophthalmologist before treatment with tryparsamide. In optic involvement, the result of injection should be carefully watched. Occasionally vomiting, slowing of the pulse and loss of consciousness may occur immediately after an injection, similar to those seen with arsenobenzene. Remote effects are shedding of the nails, albuminuria and dermatitis. Visual disturbances are seen with larger doses. If these occur, a suitable interval between injections prevents them. Doses of 3.0 gm. and over should not be given oftener than once a week. If amblyopia develops during the treatment of trypanosomiasis tartar emetic is substituted for 3 weeks. Sodium thiosulphate injections appear to be ineffective in preventing amblyopia.

Therapeutic uses. *Syphilis.* Experiments on rabbits showed that this drug possesses the power of tissue penetrability to a marked degree; extensive cutaneous and subcutaneous lesions in these animals retrogressed and healed very quickly under its effect. Tryparsamide is not effective against primary and secondary syphilis, nor against the gummata or earlier cerebro-spinal manifestations. It appears to possess the power of penetrating into the tissues, especially nervous tissues, to a much greater extent than some of the other arsenicals. It has been tried in neuro-syphilis with good results. Marked serological improvement is observed in the majority of cases of all types of syphilis but 50 or more injections are necessary, extending over a period of one year. Some cases of early paresis improve. Some authorities combine tryparsamide with weekly injections of 1 grain of mercury salicylate. There is general

agreement that in early cases of general paresis and tabes, treatment with tryparsamide is of considerable value, better results being obtained than with arsphenamine. The results, when the parenchyma is involved, are superior to those when the blood vessels and the meninges are affected, but while clinical improvement is soon manifested it requires about 80 injections of tryparsamide to render the serum reaction negative. The value of the drug is said to be due not to spirochæticidal action but to a general tonic action on the tissues. In neurosyphilis it is advisable to give courses of 8 to 15 injections of 2 to 3 gm. (not exceeding 0.04 to 0.05 gm. per kilo.) at intervals of not less than a week, with intermission of 2 months between the courses. Treatment is to be continued for several years. According to some, tryparsamide can be given safely where optic atrophy is present provided the patient is carefully watched. In cases of paresis and mania it is worthy of trial.

Trypanosomiasis. Tryparsamide is a very efficient trypanocide. Chesterman (1923) treated 40 cases in the Belgian Congo by 8 to 10 weekly intravenous injections of 3 gm. each dissolved in 10 c.cm. of water, with good results. The dose should not exceed 4 gm. and intrathecal administration is not recommended. Adults receiving less than 0.05 gm. per kilo. body weight generally relapse; children can stand comparatively much bigger doses and in these cases 0.1 gm. per kilo. can be given.

Marshall and Vassallo (1926) consider that tryparsamide gives comparatively much better results than Bayer 205 in the treatment of trypanosomiasis. Tryparsamide clears the blood in from 6 to 12 hours in doses of 1.5 gm. intravenously, in early infections due to *T. gambiense*; the peripheral blood remains free for such long periods as to suggest permanent cure. The drug is not effective in infections with *T. rhodesiense*.

Weekly injections of 2 to 3 gm. in adults have been recommended because such doses give equally good results as large and more frequent doses, and because they reduce the chances of ocular disturbance to the minimum. In the first stage of the disease a total dosage of 20 to 50 gm. suffices to produce a

cure. The blood and glands become permanently negative, there is marked clinical improvement in those cases in which the spinal fluid is only slightly changed before treatment, and it tends to become normal with the treatment. In the second stage it is necessary to give 50 to 100 gm. The patients who exhibit nervous and mental symptoms are said to show rapid and considerable improvement; in cases of moderate intensity the benefit obtained is marked and constant. The action is said to be rapid, durable, constant and is definitely superior to any other known drug. Relapses or incomplete cures are always due to extraneous causes such as insufficient dosage, irregularity of the injections and difficulties due to the patient. Toxic reactions, acute or chronic are negligible. Blindness which occurs after treatment with tryparsamide is in most cases due to previous arsenical treatment. The drug not only has curative effects but probably has prophylactic properties as well.

Tryparsamide is said to have a beneficial effect on general nutrition in addition to its parasitotropic effects, and some clinicians believe that its chief action is to build up the resistance of the body to combat infection.

Prophylactic use. Tryparsamide has not been extensively used as a prophylactic drug in sleeping sickness in man. In vaginal infections in animals (rabbits) it has a well marked prophylactic effect. This may be worth testing. Further experience of its use on a large scale is required to ascertain how far the systematic use of the drug in all the infected persons in any area will enable new infections to be reduced.

STOVARSOL

Synonyms:—Ehrlich 594, Fournau 190, Acetarstone, Kharophen, Orarsan, Osvarsan, Stovarsolan, Acetylamino-oxyphenyl-arsonic acid, Spirocid, Troposan. It contains 27.2 per cent. of arsenic.

Pharmacological action. It is absorbed rapidly, has a low toxicity and is excreted rapidly in the urine. Saullet (1927) found that stovarsol was lethal to *E. histolytica* culture within 24 hours in dilutions of 1 in

600. He noted that it was more active in the presence of liver extracts. It is a safe drug, is easy to administer, has a marked effect on the hæmopoietic system and acts as a good general tonic.

Therapeutic uses. *Syphilis.* It was first introduced into medical practice in 1921-22 in the treatment of malaria and amœbic dysentery, as a prophylactic against syphilis, and for the treatment of spirochætal infections. Administration by the mouth produced healing of primary lesions in rabbits and monkeys. In syphilis in man 1.0 gm. of stovarsol by the mouth for one week, followed by another course at the interval of a week till 12 to 16 gm. were given, healed the primary chancre. Secondary and tertiary lesions are said to have also disappeared. It is useful in the treatment of general paralysis, especially when there are megalomania or psychical disturbances. The serological reactions improve in one-third of the cases. Congenital syphilis of infants has been treated with stovarsol; the doses recommended are 0.12 gm. daily for 4 days to a total of 6.6 gm.

Yaws. 0.5 to 1.0 gm. daily given by the mouth before food on alternate days for 15 to 17 days generally clears up the lesions. Sodium stovarsol 0.5, 1.0 and 1.5 gm. may be given intravenously at intervals of 48 hours to a total of 9.0 gm.

Amœbic dysentery. Marchoux (1923) appears to have been the first to test this drug in the treatment of amœbiasis. The drug was used in those cases who had resisted emetine treatment, in doses of 0.25 gm. in pill form twice daily for a period of 10 days. Amœbæ or cysts were found in the stool even after the treatment. Petzetakis (1925) tried the drug extensively and found it an excellent remedy for parasitic infections of the intestinal tract; in infants the doses recommended up to one year of age are 0.05 to 0.08 gm. daily; from 1 to 2 years, 0.08 to 0.10 gm.; from 2 to 5 years 0.10 to 0.25 gm. daily. In chronic and relapsing cases of amœbiasis prolonged treatment is necessary and may be supplemented by injections of emetine. He found that the drug can be exhibited over prolonged period without producing any ill effects. To avoid toxic symptoms, which frequently occur with the drug, the dose should not

exceed two tablets (8 gr.) daily for 10 days or 1 tablet (4 gr.) daily for 20 days. Brown (1926) considers that stovarsol is more effective in eradicating amoebæ than emetine. Van Steenis (1927) found stovarsol less effective than emetine or yatren, but very useful against the 'minuta' type of *E. histolytica*.

Knowles (1928) in summing up the literature on stovarsol, says that it is apparent from the large series of papers that on the whole the results are not too bad. Almost every writer comments on the drug as one easy to administer and well-tolerated by the patient. On the other hand it has less powerful amoebicidal action than emetine, and some authors comment on its toxic effects. Occurrence of a measles-like rash was not uncommonly met with and cases of acute exfoliative dermatitis have been recorded after administration of stovarsol. Knowles treated 32 patients, mostly chronic, in Calcutta; the ratio of probable cures to failures in these was 1:1.1. He is of opinion that stovarsol has a definite place in the treatment of chronic intestinal amoebiasis. The ease and simplicity of the treatment are remarkable. The usual course is one tablet of 4 grains each night and morning for ten days. No toxic symptoms were observed, while the drug undoubtedly has a hæmatinic value; the patients taking stovarsol are not miserable and unhappy beings like those on emetine or emetine-bismuth-iodide treatment. The average cost of treatment is 2 to 3 rupees. It is particularly useful in chronic cases and the chance of eradication of the infection is 40 to 50 per cent. The drug was used by Knowles as an after-treatment, the relief of clinical symptoms being first obtained with emetine injections and bismuth treatment. The patient was then given a few days' rest and a ten-day course of stovarsol afterwards. This usually leads to rapid improvement in general health and the infection may be eradicated. For chronic carriers stovarsol may be followed by a course of emetine-bismuth-iodide.

Malaria. Stovarsol was first used in the treatment of malaria in 1923 and it was reported to be effective against tertian and quartan infections. Intravenous injections of 1.0 gm. of sodium stovarsol in 10 c.cm. of distilled water were found to

be effective in patients artificially and naturally infected with *P. vivax*, the parasites disappearing from the blood. The drug appeared to have an action especially on the older pigmented parasites, older schizonts and gametocytes in contradistinction to quinine, which attacks the younger forms. While stovarsol in 1.0 gm. doses produces disappearance of *P. vivax* from the blood, *P. falciparum* and *P. malariae* are not touched according to many observers. The action of stovarsol on various stages of *P. vivax* has been studied. It would appear that the parasites are only destroyed when they reach a certain developmental stage, while the younger forms are not touched. Sinton found the relapse rate in benign tertian malaria treated with stovarsol smaller than with the cinchona alkaloids. Severe rigors sometimes follow within 18 hours of injection of stovarsol in malaria, resembling those occurring with neoarsphenamine. It is possible those are due to liberation of toxin after rapid destruction of the parasites.

Quinine stovarsol is a compound of quinine with stovarsol. It causes disappearance of the crescents in from 3 to 36 days, but the schizonts are not so readily affected.

Relapsing fever. Stovarsol in doses of 1.5 gm. by the mouth is said to cure relapsing fever, the spirochaetes disappearing in 6 to 30 hours. Others have had disappointing results. It has also been used for prophylactic purposes.

Stovarsol has also been employed in the treatment of intestinal parasites such as lambliasis. Stovarsol orally and by injections has been tried against trypanosomiasis by many workers but without success.

Calcium stovarsol phosphate known as *Realphene* has been tried in syphilis with good results. It is a good general tonic.

Toxic symptoms. Cases of poisoning with stovarsol, following its administration in dysentery in 2 gm. doses daily, have been recorded. Fever was the first symptom followed 2 days later by diffuse erythema, dryness, pruritus and urticaria. Rashes appeared all over the body and on the legs and face; in severe cases it may pass on to exfoliative dermatitis. Oedema, jaundice, colic, diarrhoea, albuminuria, coryza, bronchitis, urticaria, ocular troubles, giddiness, collapse and glycosuria may occur. Acute nephritis with casts in the urine may occur after injection. The drug should not be given for more than 10 days at a time, the second course should be given after a suitable interval. In Sinton's series no toxic symptoms occurred, probably because he used

magnesium sulphate which eliminated arsenic from the gut, or possibly because the liver and kidneys were protected with glucose and alkali.

TREPARSOL

Synonyms:—Fournau 257, Sodium-3-formylamino-4-oxy-phenyl-1-arsionate, Formyphenarsine.

It is said to be suitable for administration by the mouth in 1.0 gm. doses in the treatment of malaria, syphilis, yaws, etc. Good results were reported to have been obtained in dengue when the drug was given by the mouth in doses of 0.75 to 1.5 gm. on four consecutive days. In the intestines treparsol is split up into formic acid and meta-amino-para-oxyphenyl arsenic acid which is the active principle of stovarsol and is said to act directly on intestinal parasites, specially protozoa. In combination with emetine it is said to have some effect in infections due to giardia and trichomonas, it has not been used against amoebic dysentery. Although courses extending over 4 weeks have been recommended it is not advisable to give it for more than 10 days at a time. Slight diarrhoea may occur and fatal cases have been recorded after prolonged use. Treparsol is excreted mostly in the urine.

Fournau 270 (sodium-4-acetylamino-2-hydroxyphenylarsinate). It is a white powder readily soluble in water and can be injected subcutaneously; it is painless, produces no local reactions and is rapidly absorbed. The drug has been tried in human trypanosomiasis but is not so effective as tryparsamide. It has been tried for prophylactic purposes in animals but is less efficient than tryparsamide.

Fournau 269 & 417. (4-amino-2-hydroxyphenylarsinic acid and 4-formylamino-2-hydroxyphenylarsinic acid). Both these drugs can be given by the oral route. Fournau 417 has a chemotherapeutic index of 1 : 16 when given by the mouth and 1 : 5 when given subcutaneously. These drugs are at present under trial.

Acetylarsan (hydroxy-acetylaminophenylarsinate of diethyl amine) can be given by intramuscular and subcutaneous injections, but headache, vomiting and diarrhoea are frequently produced; erythema, albuminuria, and jaundice may occur. In trypanosomiasis 12 gm. are given in 16 injections of 0.75 gm. each at intervals of one week; the results are inferior to tryparsamide. The primary and secondary lesions of syphilis are said to be favourably influenced. One to 3 injections of 12 to 50 mgm. per kilo. produce rapid results in primary, secondary and tertiary yaws. In relapsing fever it is considered more effective than arspenamine.

B. R. 68. This drug, prepared by Binz and Rath (1927) differs from others in that the arsenic is not linked to a benzene nucleus. The drug produces febrile reactions and vomiting and is useless in infections due to *T. rhodesiense*.

B. R. 34 is said to be effective in doses of 0.2 gm. intravenously freeing the blood of trypanosomes.

B. R. 34A. is a pyridine preparation of arsenic and is effective against *T. brucei* infections in mice. Its chemotherapeutic index is 1: 20.

Hoechst 2754. This compound is said to be closely related to tryparsamide and can be given intravenously in 2 gm. doses. It is said to have a definite action in the second stage of trypanosomiasis but is apt to produce nephritis.

Trivalent Compounds of Arsenic

SALVARSAN

Synonyms:—Kharsivan, Dioxy-diamino-arseno-benzol dihydrochloride, Arsenobenzene, Arsenobenzol, Arsphenamine, Arsenobillon, Arsen-phenolamine, Amino-arsenophenol, Ehrlich-Hata 606.

Salvarsan was first prepared by Bertheim and tested by Ehrlich and Hata in 1910. The dose for women is 0.3 to 0.4 gm. and for men 0.4 gm. in 200 c.cm. of solution medium. It is prepared from atoxyl by reduction and combination of two of its molecules to form a trivalent dihydroxyl-diamino-arsenobenzene which is a stable preparation. It is a yellow crystalline powder containing 31.5 per cent. of arsenic; it is readily oxidised in the air and so is kept in vacuum tubes. Salvarsan though it does not kill spirochaetes *in vitro* has a very pronounced effect on these organisms *in vivo*. It is fifty times less toxic for experimental animals than mercury. The M.L.D. for mice is 143 mgm. per kilo. and for rabbits 100 mgm., when given intravenously. In rats showing a trypanosome count of 150,000 to 250,000 per c.cm. of blood, temporary sterilisation could be effected with doses of 6 mgm. and permanent sterilisation with doses of 8 to 12 mgm. per kilo. Mice infected with the spirochaetes of relapsing fever were sterilised with 10.6 mgm. per kilo. and rabbits inoculated with syphilis were cured with 23.5 mgm. per kilo. given intravenously.

Salvarsan has the disadvantage of having an acid reaction in solution and therefore has to be neutralised at the time of

use. For this reason it has been mostly replaced by neo-salvarsan. A solution which is not fully neutralised or one which is over-alkalinised is depressant for the heart. In feeble patients or when the central nervous system or the heart is affected smaller doses should be given. Generally a course of 4 to 8 doses is recommended, the injections being given at intervals of 8 to 10 days, often in conjunction with mercury.

Neutralisation is best effected by adding to the salvarsan solution 15 per cent. caustic soda solution to precipitate the base (0.28 c.cm. for 0.3 gm of the drug) ; dilute with a little 0.5 per cent. saline and then add just enough caustic soda solution to dissolve (about 0.6 c.cm. in all) ; finally dilute to 300 c.cm. with 0.5 per cent. saline solution.

NEO-SALVARSAN

Synonyms :—Neo-kharsivan, Ehrlich 914, Novarsenobenzol, Novarsan, Novarsenobillon, Metarsenobenzol, Neo-arsenophenolamine, Sodium dioxy-diamino-arsenobenzene-methanesulphonate.

This is a condensation product of salvarsan. It differs from salvarsan in that it is not a combination of dioxy-diamino-arsenol-benzol with HCl but with sodium methane sulphonate. It is a yellow powder, readily soluble in water, giving a neutral solution. It is a stable preparation and readily dissolves in water forming a neutral solution, it can therefore be injected intravenously in concentrated form. The dry powder must contain not less than 18 per cent. or more than 21 per cent. of arsenic; according to U.S.P.X. it should not contain less than 19 per cent. of arsenic.

The experiments for testing the action of neo-salvarsan were chiefly conducted on the spirochaetes of relapsing fever in rats and mice, and subsequently in fowls and also on the treponema of syphilis. It was found that a single non-toxic dose freed the animals completely from spirochaetosis and protozoa. *In vitro* experiments show that during the first 10 hours even

1 in 100 concentrations have no effect on the spirochætes, but after 15 hours there is marked reduction in their number and eventually all are destroyed. The maximum dilution for killing them was 1 in 200,000 as compared with 1 in 2,500 for *Bact. coli*.

When injected intravenously into rats, neo-salvarsan is about two and a half times less toxic than salvarsan. The maximum tolerated dose of the American product in rats is 254 mgm. per kilo. body weight, in mice it is 250 mgm. and in rabbits it is 200 mgm. when given intravenously. The average minimum curative dose of neo-salvarsan for rats infected with *T. equiperdum* is 4 to 6 mgm. intramuscularly and for rabbits inoculated with syphilis 30 to 40 mgm. intravenously. The hydrogen-ion concentration of neo-salvarsan is 7 to 7.4 which is the same as that of the blood, while that of a properly alkalised solution of salvarsan is more than 9. It therefore causes less biochemical disturbances in the blood and tissues. Although some syphilologists still regard salvarsan as being superior to neo-salvarsan, the latter is nevertheless more widely employed and exerts practically the same favourable influence upon the disease and certainly possesses a greater factor of safety.

Dosage. This should be regulated according to the general condition of the patient. In the male adult the starting dose of salvarsan is usually 0.2 gm. which is increased by 0.1 gm. at every successive injection till a maximum of 0.6 gm. is attained. For females, the starting dose is 0.2 gm. and a maximum of 0.4 gm., for children 0.1 to 0.3 gm.; for infants 0.02 to 0.1 gm. The dose of neo-salvarsan is about $1\frac{1}{2}$ times that of salvarsan. The ordinary course is 6 to 8 intravenous injections given at intervals of 7 to 10 days. With very early cases, the first 2 or 3 injections may be given 3 or 4 days apart. The patient is allowed 6 to 8 weeks' rest and then another course is given and this in early cases may be repeated till 3 or possibly 4 courses have been given. Mercury is also given with the courses and semi-annual courses of mercury may be kept up for 3 years

Co-ordination Compounds

The chemotherapeutic effect of co-ordination compounds of salvarsan and neo-salvarsan equals that of salvarsan and neo-salvarsan.

Silver salvarsan or **silverarsphenamine** is a metal arsenobenzene compound. It is a brownish-black powder, readily soluble in water, giving an alkaline solution. It contains 22.5 per cent. of arsenic and 14 per cent. of silver, probably in the form of silver oxide. It is given intravenously in doses of 0.1 to 0.2 gm. for women and 0.25 gm. for men at weekly intervals. In feeble patients begin with 0.05 gm. or 0.075 gm. Generally 0.1 gm. is dissolved in 10 c.cm. of sterile water making a 1 per cent. solution. Clinically 0.1 gm. of this drug corresponds to 0.3 gm. neo-salvarsan. Sodium silver salvarsan is another preparation in which the silver is not combined with salvarsan but exists in a colloidal state.

Neo-silverarsphenamine or **neo-silver salvarsan** is a molecular compound of neo-salvarsan and silver and is a brown powder. Sodium silver neo-salvarsan is yet another preparation. Neo-silver salvarsan is said to be about half as toxic as silver salvarsan and slightly more toxic than neo-salvarsan; its maximum tolerated dose is 278 mgm. per kilo. of mice as compared with 167 mgm. of silver salvarsan and 370 mgm. of neo-salvarsan. These compounds have been used in the treatment of syphilis and produce remarkable results on visible syphilitic lesions. With these compounds the characteristic and often nauseating garlic-like odour is absent. They have not been known to produce argyria. It was thought that silver compounds of salvarsan were probably twice as effective as neo-salvarsan in similar doses, but this has not been proved. In multiple sclerosis silver salvarsan, in doses of 0.05 gm. increased to 0.2 gm. twice weekly, is said to be an effective remedy.

The silver compounds should be given with caution in cardiac disease and diseases of the liver and kidney and when there is a tendency to skin disease.

Sulpharsphenamine. Synonyms:—Sulfarsenol, Sulpharsenobenzene, Kharsulphan, Myosalvarsan.

This was originally a French preparation. It is a fine yellowish powder which dissolves easily in water giving a neutral solution which can be given intravenously, subcutaneously or intramuscularly. It contains 20.7 to 23.6 per cent. of arsenic and 8.7 to 12.8 per cent. of sulphur. Chemically it is dioxy-diaminoarsenobenzene-dimethylene sulphonate. Dose 0.12 to 0.18 gm. for the first injection in 2 to 3 c.cm. of distilled water, gradually increased to 0.45 to 0.6 gm. For intravenous injections 0.06

gm. is the starting dose but Harrison (1921) does not recommend the intravenous use of the drug as dermatitis and other untoward effects are more likely to follow by this route. The M.L.D. (minimum lethal dose) of this drug in white rats ranges from 320 to 480 mgm. and the M.E.D. (minimum effective dose) from 15.9 to 31.5 mgm. per kilo. when given intravenously. When given intramuscularly or subcutaneously, the M.L.D. is 400 to 700 mgm. and the M.E.D. is 15.6 to 34 mgm. per kilo. body weight. It is the only arseno-benzol compound on the market which appears to be equal in efficiency to salvarsan or neo-salvarsan in the treatment of syphilis when given by the hypodermic or intramuscular route; it is therefore useful in children and for obese persons with veins difficult to find; such strong solutions as 20 to 30 per cent. can be given without untoward symptoms. The drug is useful in patients who develop shock or nitritoid reactions. It is therapeutically just as effective and is specially well borne by children with congenital syphilis. Dermatitis and jaundice may be produced by it, but acute symptoms such as nausea, vomiting and diarrhoea are less common; the incidence of general reactions is also lower.

Harrison (1923) recommends it when myocarditis and aneurism are present. It is specially indicated in the treatment of congenital syphilis, in gonorrhoeal arthritis and puerperal septicæmia. The following table from Martindale gives the dosage for a course in primary syphilis for an average adult.

Day	Dose	Quantity of sterile water
1	0.12 to 0.18 gm.	2 to 3 c.cm.
3	0.18 to 0.3 gm.	3 to 5 c.cm.
5	0.30 to 0.42 gm.	5 to 7 c.cm.
8	0.42 to 0.6 gm.	7 to 10 c.cm.
13	0.48 to 0.6 gm.	8 to 10 c.cm.
19	0.54 to 0.6 gm.	8 to 10 c.cm.
25	0.6 gm.	8 to 10 c.cm.

After the 40th day, do a Wassermann test and a second course to be started on the 61st day in sero-negative primary

cases; in sero-positive primary cases 3 or more courses may be necessary.

Thiosarmin or disodium-dioxy-diamino-arsenobenzene-methylene sulphonate has been prepared in the Brahmachari Research Institute, Calcutta. It is very closely allied to other sulpharsenobenzene compounds such as sulfarsenol, kharsulphan, sulpharsphenamine, etc.

Thiosarmin is a light yellow powder readily soluble in water, almost neutral in reaction and having a hydrogen-ion-concentration of 7.2 to 7.4. It is fairly stable and does not change its colour, even on standing for 48 to 72 hours. When heated it decomposes without melting. The arsenic content varies from 19.5 to 25 per cent.

Toxicity. The toxicity of the compound is very low and compares favourably with similar preparations. Denham-White and Brahmachari (1933) found that the toxicity of thiosarmin, sulfarsenol and sulpharsphenamine is almost the same in experimental animals. Given intravenously in white rats the maximum tolerated dose of thiosarmin was 300 mgm. and the minimum lethal dose 490 mgm. per kilo. of body weight. The minimum lethal dose in the author's series of experiments, when given intravenously in a 2 per cent. solution in white mice, was found to be between 425 to 450 mgm. per kilo. of body weight.

Thiosarmin is indicated in all stages of syphilis. Local lesions are said to heal up after a few injections and the results of the Wassermann reaction are very encouraging. The dosage recommended in syphilis is to begin with 0.15 gm., increased by 0.15 gm. in subsequent injections to a maximum single dose of 0.6 gm. Below 16 years $\frac{2}{3}$ full dose is given and children below that age should receive proportionate dosage. The drug should be dissolved in redistilled water, boiled and cooled. A 10 per cent. solution is slowly injected intramuscularly in the gluteal region. It can also be given subcutaneously or by the intravenous route.

Amongst the advantages claimed for the drug are absence of reaction, the temperature does not rise, and the danger of nitritoid crises or anaphylactoid conditions is negligible. In

some cases, however, signs of intolerance follow injections of thiosarmin which call for immediate suspension of the treatment. Cardiac degeneration, nephritis, severe diabetes, cirrhosis of liver are contraindications to its use.

Bismarsen or bismuth arsphenamine sulphonate. It is one of the co-ordination compounds of arsphenamine, the bismuth being linked to the arseno group in the same way as silver, gold, etc., to their respective compounds. Chemically it is trisodium-3-amino-4-hydroxyphenylarseno-n-methylene-sulphonate dibismuth, having the empiric formula $C_{21}H_{21}O_{12}As_2Na_3S_2N_3Bi_2$. Bismarsen is a brownish-yellow amorphous powder freely soluble in cold water. The arsenic content of the preparation ranges from 12 to 15 per cent. while bismuth occurs in proportion of 23 to 25 per cent. One great advantage of the drug is that it can be given intramuscularly, thus avoiding many of the technical difficulties of intravenous arsenic medication, and at the same time the combination of bismuth and arsphenamine enhances the spirochæticidal activity to an extent greater than the summation of these two drugs separately. Kolmer (1930) found that in rats infected with *T. equiperdum*, the minimum curative dose by the intravenous route was 0.012 gm. per kilo. and by intramuscular injection, 0.015 gm. per kilo. body weight. In experimental investigation in rabbits infected with syphilis, the minimum single curative dose was approximately 0.015 gm. per kilo. by intravenous route and from 0.015 to 0.030 gm. per kilo. by intramuscular injection. Stokes and others (1931), in their appraisal of this new synthetic compound, concluded that it is a safe, relatively non-toxic and efficacious drug for administration in syphilis. They consider it a valuable substitute for arsphenamin in reactive patients, though slower in action. Herxheimer's reaction and nitritoid crisis are very rare; the effect on the Wassermann reaction is very encouraging and the proportion of all forms of relapse in a series of early syphilitic cases was 12 per cent. as compared with from 20 to 40 per cent. in cases treated with other drugs.

The method of administration in syphilis is to give it intramuscularly in 0.2 gm. doses, dissolved in 1 c.cm. of

distilled water, to which 2 minims of 2 per cent. solution of butyn are added to minimise the local painful reaction. Generally 4 or 5 courses are given, each course comprising about 8 injections, twice weekly, and the interval between each course being one month. The occurrence of dermatitis or jaundice during the treatment necessitates the stoppage of all injections. Special value has been given to bismarsen in the treatment of cardiovascular syphilis for its tissue-soluble properties and for its effect on Wassermann fast syphilis.

Mode of action of organic arsenicals. Ehrlich's original idea was that these drugs had a simple parasitocidal action and that certain chemical chains in the drugs had a selective chemical affinity for certain side chains in the protoplasm of the organisms and therefore the organisms were killed without harm to the host; this idea has now been given up. That organic arsenical compounds are converted into trivalent oxides before parasitocidal action is brought about, has been experimentally shown. Several drugs have no action upon trypanosomes *in vitro*, but have a considerable trypanocidal action *in vivo* and it has been proved by experiments that these drugs are in many cases changed in the body from relatively inactive to more active forms. Hata working in Ehrlich's laboratory showed that arseno-benzene does not kill spirochaetes *in vitro*. In the Hygienic Laboratory, U.S.A. Public Health Department, it was shown that a partial oxidation of arsenobenzene occurs. The compounds of R.As.=O type (arsenious acid, arsenoxide) in dilutions of 1 in 10,000 render trypanosomes non-infectious *in vitro* and kill the trypanosomes in rat's blood immediately after injection. The compounds of R.As.=As.R. (salvarsan) type in similar doses have little action on trypanosomes for the first hour and do not kill 90 per cent. of the parasites after 2 or 3

hours; pentavalent compounds of R.As. $\begin{array}{c} \text{OH} \\ \diagup \\ \text{O} \\ \diagdown \\ \text{OH} \end{array}$ type are still less

effective. It seems that it is the persistent effect of minute quantities of the oxide, far below the concentration immediately lethal *in vitro*, maintained for sometime, which is responsible for cures. From this point of view the superior activity of arseno-compounds, which form a depot from which minute quantities of the oxide are continuously given off, can be understood. Dobell and Laidlaw (1926) have shown that persistence of action for long periods is a very important point in the amoebicidal action of emetine and probably the same is true of the arsenicals. In toxic doses the first class of compounds produce immediate toxic effects while the other two classes only produce toxic effects after considerable delay. Salvarsan incubated at 37°C. with animal tissues for 3 hours produced immediate effects upon rat trypanosomes and its toxic action

was intensified. Salvarsan is found to destroy cultures of spirochaetes in the test tube only in concentration of 1 in 1,000 but incubation and digestion by the tissues change salvarsan into bodies of the nature of arsenoxide by which both the spirochaeticidal and toxic action are intensified. In the body, trivalent compounds have very little immediate effect on trypanosomes. After 24 hours these compounds produce death in extremely low concentration—one part in several hundred millions.

A new conception of the arsphenamine treatment of syphilis is offered by Anwyl-Davis. While watching *S. pallidum* for days by the dark ground method he found that when bathed in salvarsanized serum they gradually lose their normal appearance, become ghost-like, fragmented and paralysed and in about five days apparently die. About 5 or 6 hours later they recover their normal appearance, are revived, regain their spiral and motility and become as normal and as active as controls that have not been 'doped.' This strongly suggests that arsphenamine should be injected at intervals of five days or less instead of waiting for the customary week. The organisms should be attacked with fresh drug when their vitality is lowest so that they may not multiply or develop resistance.

These drugs are examples of compounds whose therapeutic efficiency is due to changes which take place in them in the body. Their therapeutic efficiency is estimated by determining the ratio between the sterilising dose and the tolerated dose though this is liable to error on account of the resistance of different species of trypanosomes and also of the animals. Voegtlin and his associates (1923) have advanced the theory that arsenic in the form of trivalent oxides ($\text{R.A.s.}=\text{O}$) is the active form and is a specific poison for the sulph-hydryl SH groups of compounds like glutathione and possibly other SH compounds present in the protoplasm of the parasites. The glutathione group is concerned in the oxidation and reduction processes in the living cells and Hopkins and Dixon (1921) showed that compounds containing an SH group, such as the reduced form of glutathione, sodium-thioglyco-collate, etc. counteract the toxic action of arsenoxide on these trypanosomes, both *in vitro* and in the circulating blood, presumably by an union of the arsenic with these compounds by means of their SH group, before the arsenic has united with the SH group of the parasites. The organotropic action is also reduced. Arsenic therefore in the form of an aromatic arsenious compound may be regarded as a specific poison which acts by combining with the SH compound in the protoplasm and its effects can be counteracted by introducing the SH compound artificially, to take the place of those present in the protoplasm. The organic compounds of arsenic are examples of drugs which are introduced into the body in a relatively inert form and are changed by the body tissues to therapeutically powerful compounds. The relative activity of different

organic arsenicals is given in table modified from Clark's Applied Pharmacology (1933).

Compound.	Percentage of arsenic	M.L.D. for rat*	M.C.D. in rat infected with <i>T. equiperdum</i> *	Ratio $\frac{\text{M.L.D.}}{\text{M.C.D.}}$
1. Arsenic acid ...	53	50	37.5	1
2. Atoxyl (arsanilic acid) ...	27.2	150	37.5	4
3. Arsenious acid ..	69	7	7	1
4. p-Hydroxy-m-amino-phenyl-arsen-oxide ...	31.8	10	0.75	13
5. Salvarsan. ...	34	75	2.0	37
6. Neo-salvarsan .	21	100	3.0	33

STANDARDISATION OF SALVARSAN AND ALLIED COMPOUNDS

Standards of toxicity of salvarsan and its allies. All trivalent organic arsenicals are highly reduced bodies. If reduction is carried out with insufficient vigour they become rapidly contaminated with a much more toxic oxidation product, arsenoxide (3-amino-4-hydroxy-phenyl-arsenic oxide). One of these compounds is 20 times more toxic than the pure hydrochloride of an arseno compound. It is impossible even by the most careful production, to exclude completely the more toxic oxides and commercial samples contain from 0.4 to 5 per cent. of arsenoxide. Oxidation may also occur during the process of preparation of solutions. It is the duty of the manufacturers to see that no batch of this product contains these in unsafe proportions. The extent of contamination can be chemically determined with some degree of accuracy. There are also indications that other toxic products of unknown constitution may arise through uncontrollable accidents in preparation. The Board of Trade has made a condition that all samples prepared should be subjected to biological tests by an approved authority. In addition, every sample is further tested by intravenous injection in rabbits in doses only slightly less than that which may be expected, according to Ehrlich's publication, to be lethal for the animals. In order to ensure that arsphenamine preparations are not toxic and are of definite therapeutic value, certain standardisation tests have been introduced. Every batch prepared has to be tested. Arsphenamine has now been discarded in favour of neoarsphenamine preparations, and tests have been evolved for this. The chemical composition of this product of manufacture has never corresponded closely with the theoretical formula. By slight modifications of manufacturing process, substances of low toxicity can be produced to pass the official

*Dose expressed in cubic centimetres of N/10 solution of arsenic per kilo. of bodyweight.

tests. Lowering of toxicity however seriously weakens the therapeutic efficiency. Tests for therapeutic standardisation have therefore been introduced.

Rats and mice infected with trypanosomes are preferred to fowl spirochaetes of relapsing fever, since trypanosomiasis in the latter assumes an acute course resulting in death of the animal. *T. equiperdum* is preferred to other trypanosomes. The number of trypanosomes per c.mm. of blood of a seed rat is counted, an inoculum of definite strength is prepared and this is injected intraperitoneally. In 24 hours these rats will have a definite number of parasites per c.mm., those having 100,000 to 150,000 per c.mm. are preferred. The drug to be tested is then dissolved in distilled water and a known quantity of the drug is given intravenously. The minimum effective dose (M. F. D.) is the dose of the drug required to bring the trypanosome count to negative within 24 hours, i.e., the dose of the drug which kills 100,000 to 150,000 trypanosomes. Greater accuracy is obtained if the blood is not only examined 24 and 72 hours after injection, but also 21 days later. The question of drug resistance has to be borne in mind.

Dale, White, Burn and others in England use mice instead of rats. The strain of *T. equiperdum* is propagated in rats, and mice are infected by an intraperitoneal injection of 0.1 c.cm. of an emulsion of rat's blood in 1.0 per cent. sodium citrate solution, so that 7 to 8 million of trypanosomes are injected. Ten days later the mice showing 100,000 to 500,000 trypanosomes per c.mm. are selected. The smallest dose which causes a complete disappearance of trypanosomes within 72 hours is termed the minimal curative dose. Dale and his co-workers have shown that there is a very close parallelism between the action of these drugs on trypanosomes and spirochaetes in man.

Toxicity tests. The International Conference on Biological Standards met at Geneva in 1925 and resolved that arsphenamine, its metallic derivatives, e.g., silver arsphenamine and its sodium salt, neoarsphenamine and its metallic derivatives and sulpharsphenamine should be standardised.

British test. (1) Neoarsphenamine 0.3 mgm. per gm. body weight is injected in five mice. If not more than one mouse out of 5 dies in three days the batch is passed for issue, if more than two die it is rejected. (2) If two die on the first test, a second test is carried out with five mice and 0.4 mgm. per gm. is given from a fresh ampoule. If not more than two mice die it is passed for issue.

American test. Arsphenamine. In the official method prescribed by the Hygiene Laboratory of the United States Public Health Service, white rats weighing from 100 to 150 gm. are employed. For each toxicity test, not less than five rats are used, and at least 60 per cent. of the animals injected must survive at least 48 hours after injection of less than 120 mgm. per kilo. of body weight of arsphenamine. This

dose is about 12 times larger per kilo. body weight than that ordinarily administered to human beings in a single dose (0.8 gm.). The total arsenic content should not be below 30 per cent. nor above 32 per cent.

Neo-arsphenamine and sulpharsphenamine. The total arsenic content should not be below 18 per cent. nor above 20 per cent. The drug should be freely mobile in the ampoule and should be readily soluble in cold water. The rats must survive seven days after an injection of 240 mgm. per kilo. This is 16 times the dose given to adult human beings. In cases of sulpharsphenamine, silver arsphenamine and silver neoarsphenamine the maximum tolerated dose should not be less than 140 and 180 mgm. per kilo. body weight respectively, by intravenous injection. Generally the compounds are considered safe for human being if animal tests show that these medicaments are borne in doses at least ten times larger than the amount required to be given according to body weight.

German test. Of three sets of five mice each receives from three different ampoules 0.37 mgm. per gm. 70 per cent., *i.e.*, 11 out of 15 must survive. With 0.42 mgm. per gm. body weight 50 per cent. must survive.

Japanese test. Ten mice are used and two-thirds, *i.e.*, seven out of ten must survive with a dosage of 0.27 mgm. per gm. The Japanese and American tests are slightly more lenient than the German tests.

It may be emphasised again that toxicity does not guarantee therapeutic activity and highly toxic substances may be therapeutically inactive. The specimens should, therefore, be tested both as regards their toxicity and therapeutic activity before being placed on the market.

Besides the oxides, methyl alcohol which is used in their preparation also occurs as an impurity, but it is in such small amount that its toxic effects can be ignored. The same is true of inorganic impurities like sulphites, sulphates and sodium chloride which may be present. According to some, sodium chloride may be responsible for producing fever.

CHAPTER XXX

TOXIC EFFECTS OF ARSENIC COMPOUNDS

Acute poisoning. Inorganic arsenic, when taken by the mouth in large doses produces severe gastro-intestinal irritation, vomiting, painful profuse watery diarrhoea (rice water stools), suppression of urine, intense thirst, prostration and collapse ; even when given hypodermically the drug produces its action on the epithelium of the gut, producing fatty degeneration, necrosis and ulceration. The symptoms usually appear within half to one hour after it is taken by the mouth. In fulminant cases, the accumulation of blood from the general circulation into the splanchnic area on account of capillary paralysis, may produce collapse and death without producing any of the usual symptoms. At the post mortem the stomach and intestines are found inflamed and there are patches of softened mucous membrane. If the patient survives long enough, fatty degeneration of the liver, kidney and heart is seen.

Fatal doses of white arsenic vary with the solubility of the preparation. Five to 50 mgm. of the trioxide produce toxic symptoms, while 0.1 to 0.3 gm. are fatal, but recovery may occur after much larger quantities. It has been shown that coarseness or fineness of the powder is an important factor in its toxicity, a solution of the oxide being 500 times as powerful as the coarse powder in the production of emesis.

Chronic poisoning. The symptoms which appear first are loss of appetite, nausea, vomiting, colic, and mild diarrhoea ; swelling of joints, peripheral neuritis, weakness, tremors of muscles, ataxic gait, muscular atrophy, bronzing and patchy pigmentation of the skin, darting pains in the limbs and muscular paralysis may occur. Persistent capillary paralysis produces diarrhoea and cedema ; sensation may be dulled and blindness may be produced. The endothelium of the capillaries, later the intestinal epithelium and finally the cells of such organs as the liver, kidneys, and the heart undergo fatty degeneration. Arsenic is quickly absorbed and is slowly excreted ; it is therefore

a cumulative poison. Pigmentation of the skin, dermatitis and peripheral neuritis commonly occur in chronic poisoning.

Treatment of arsenic poisoning. Acute arsenic poisoning is usually fatal, and therefore treatment should be started as early as possible. Elimination of the drug by emetics, lavage with warm water or purgation should be tried at the first instance. Chemical antidotes are not of much value. Ferric hydroxide with magnesium oxide was long considered the best antidote, the ferric hydrate and arsenic forming an insoluble compound. It is now known that the antidote is not effective to the same extent as was believed and that its administration only gives a slightly smaller percentage of fatalities. In any case, as this antidote is harmless, it may be given a trial provided that it is promptly followed by effective evacuation.

Chronic arsenic poisoning does not require prompt and energetic treatment. The administration of arsenic in any form should be stopped. Rest in hygienic surroundings, a milk diet and alkalies are indicated. Symptomatic measures against vomiting, diarrhoea, etc., and stimulants whenever necessary may be exhibited.

Toxicity of organic compounds. Organic arsenicals such as salvarsan and its substitutes are usually injected in doses as high as can be tolerated and therefore toxic effects are not uncommon. These are generally due to three causes; in order of importance they are—

1. *Pathological states and susceptibility of the patient.* Fear, nervousness, endocrine disturbances, vagotonia, pathological changes produced by syphilis, non-syphilitic diseases, mercury, etc., play an important part. Natural or acquired hypersensitiveness to arsenical compounds is another important factor.

2. *Errors in method of administration.* Failure to make proper solutions, *e.g.*, making them over-acid or over-alkaline, use of defective saline solutions, excessive dilutions, intravenous injection, oxidation of the solution, emboli of the undissolved drug, cotton, air, etc., are factors of some importance.

3. *Properties of the drug itself.* The solutions may have toxic physical properties, agglutination of erythrocytes or

precipitation of plasma may occur or hæmolysis may be produced. Oxidation of the drug may occur or toxic impurities may be present.

With all these possible causes of toxic reaction it is not surprising that various undesirable symptoms are produced. Some degree of systemic reaction occurs in 0.5 to 15 per cent. of all injections, but although they are alarming they are not often dangerous. The fatality rate in a German clinic (1920) was reported to be 1 in 63,000 if the dosage was below 0.6 gm., and 1 in 3,000 if it was above. The danger can be reduced by using a reliable drug, proper technique and careful examination of the patient. The symptoms may be divided into three groups.

A. Immediate reactions. In the great majority of cases after intravenous injection of neo-salvarsan and sulfarsenol by the technically correct method no untoward effects are noticed. The first effect mentioned by the patient is a peculiar odour, and metallic taste. This effect is probably due to the circulation of the drug in the mucous membrane of the nose and salivary glands and is noticed soon after the injection. Chewing of flavoured gum or cloves during injection does away with this. Not infrequently the patient experiences a feeling of fullness in the head, and slight flushing of the face which may only last a few minutes or less; these are due to the action of the drugs on the vasomotor system and are less marked with neo-salvarsan and sulfarsenol than with salvarsan. Slight perspiration and a feeling of faintness may be noticed. Nausea and vomiting sometimes occur half an hour after the injection in neurotic patients. Intramuscular and subcutaneous injections rarely produce nausea and vomiting and the other symptoms are as a rule absent. The more severe immediate reactions are as follows:—

1. Acute physico-hæmoclastic reactions occur with salvarsan solutions, and these are due to errors in neutralisation and the symptoms are the result of widespread embolism and infarction, especially of the lungs, and cardiac dilatation; clumps of agglutinated erythrocytes are found in the heart and in the intima of blood vessels. During injection the expression of the patient's face becomes drawn, hiccough or short spasmodic cough may

develop. Dyspnoea and suffocation ensue, the pulse becomes rapid, feeble and irregular; pain and constriction in the chest occur due to emboli in the lungs; convulsions may occur due to emboli in the brain; no demonstrable symptoms are produced by embolism of the liver, spleen, kidney and other organs. Broncho-pneumonia and pulmonary embolism may develop after an interval. The patient becomes anxious, expresses a fear of approaching death; coma may follow from cerebral anæmia. The patient may recover within $\frac{1}{2}$ to 2 hours or die. The cause of this acute crisis is unknown though coagulation of the blood proteins has been suggested. There is no evidence to support this, but agglutination of red blood cells may occur *in vivo* as a result of injection of solutions of arsphenamine, and multiple emboli have been noted in the lungs.

The treatment in these cases, is to lay the patient flat on his back and to give 1 to 2 minims of 1 in 1000 solution of adrenalin intravenously; for less severe reactions give 0.5 to 1.0 c.cm. intramuscularly. Atropine sulphate 1/50 grain may be given intramuscularly for stimulating the circulation. Intravascular agglutination can be prevented by injecting arsphenamine with a protective colloid such as gelatine.

2. Acute vasoparetic reactions or 'nitritoid crises,' so called by Milton (1912) because the symptoms and lesions resemble the inhalations of amyl-nitrite. These reactions are produced by intravenous injection of many substances and are common among individuals suffering from symptoms of adrenal insufficiency or thyroid disturbances. They have been attributed to the disturbance of the sympathetic system, but it is more likely that they are due to the toxicity of the drug or abnormal changes in the capillaries or a combination of the two. The symptoms occurring immediately after or during injection are flushing of the face, dilatation of the pupils, increased pulse rate and dimness of vision. There may be pain in the gums and teeth. In more severe cases, the lips and tongue become swollen, there is a feeling of constriction in the throat and upper part of the chest and dyspnoea; a tingling sensation in the extremities, congestion of the conjunctiva and lachrymation are always present. The patient may fall, if standing when the re-

action comes on. In still more severe cases there may be urticaria, either limited to portions of the body or generalised over the limbs and trunk; profuse perspiration, vomiting, retching, loss of sphincter control and possibly loss of consciousness which may last several hours. These symptoms, though rare, occur in a certain percentage of cases after each injection. Silver salvarsan, unless injected very slowly, almost always causes vasomotor symptoms. The face becomes pale, the pulse feeble, and vomiting may ensue. In another type of reaction rigors and headache occur; it is more common after the first than subsequent injections. Occasionally vomiting is followed by severe diarrhoea a few hours after the injection. Herpes labialis may occur. In mild cases the patient may feel nothing but fright. The symptoms can all be explained by sudden dilatation of blood vessels especially the capillaries. Extreme cerebral and meningeal congestion may occur causing apoplexy. In mild cases there is only headache and vomiting and these soon pass off.

Although the symptoms described are very alarming they are rarely fatal. Cases of cardiac syphilis with aortic insufficiency and myocarditis are specially liable to develop alarming symptoms with sudden syncope after arsphenamine. In these cases cold sweats, gasping respiration, pallor, bradycardia and low blood pressure are associated with acute cardiac damage.

Various explanations have been suggested to account for the immediate vasomotor disturbances. As adrenalin relieves those symptoms, it was thought that insufficiency of the adrenal glands might be the cause. Another explanation is that a precipitate is formed. None of these hypotheses are supported by experimental data. The theory most favoured is that the symptoms resemble anaphylactic shock, and many of these certainly seem to be those due to liberation of histamine and histamine-like substances.

Treatment. If symptoms appear the patient is made to lie flat and adrenalin 0.5 to 1 c.cm. of a 1 in 1000 solution is given intramuscularly at once or it may be used as a prophylactic before the injection. Pituitrin may be given with adrenalin or by itself, atropine sulphate 1/50 gr. subcutaneously relaxes the bronchi

and relieves dyspnoea. In severe cases of coma give adrenalin intravenously. Ephedrine is said to be specially useful in preventing vasomotor paralysis. Fractional injection, *i.e.*, 1/10 of the dose an hour before the full dose, may be adopted as a prophylactic measure. In animals, injection of caesium eosinate prevents the symptom of anaphylactic shock and 15 c.cm. of a 6 per cent. solution prevents shock in man; neoarsphenamine may be dissolved in this solution. Sometimes symptoms of increased cranial pressure or tension headache occur. In these cases magnesium sulphate should be given internally or by rectal enemata to produce dehydration. If symptoms of encephalitis appear the pressure may be relieved by drawing cerebro-spinal fluid, and adrenalin may be given.

B. Early reactions. These generally start in 1 to 4 hours, but may occur within 24 hours after injection. There is fever, headache, protein or colloidal shock; accidents of injection such as phlebitis and thrombosis, also come under this heading. The kidneys may be involved and albumin and casts may be found in the urine.

Gastro-intestinal symptoms occur if injections are given soon after a meal. These are nausea, vertigo, headache, thirst, vomiting and diarrhoea. Symptoms usually stop in 12 to 24 hours but may continue for several days. Adrenalin is also beneficial in these cases. Protein or colloidal shock produce fever, perspiration, chilliness or even a rigor.

C. Late reactions. These occur from one day to several weeks after the injection. These are hæmorrhagic encephalitis, dermatitis, neuritis, Herxheimer's reaction and jaundice. Hypersensitiveness to these reactions may be acquired. It is not infrequently seen that patients who have one or more courses of arsenical compounds, suddenly or gradually begin to develop immediate or early toxic reactions after small doses, *e.g.*, nausea, vomiting, flushing, occurring immediately after injections. The skin tests are negative so that the effect is not cumulative.

Jarish Herxheimer's reaction. This type of reaction has been attributed to liberation of luetic toxins from spirochaetes killed by the drug. The luetic lesions especially of the trunk,

show bright red erythema lasting a few days. Generally they cause little inconvenience, but it is conceivable that analogous reactions in cerebral and hepatic gummata may be dangerous.

Cerebral symptoms. Hæmorrhagic encephalitis occurs especially after large doses or when ordinary doses are given in quick succession. The symptoms start 2 to 5 days after injection with severe headache, vomiting, weakness, oedema of face, muscular twitching, dyspnoea, epileptiform convulsions, clonic spasms and suppression of urine. Loss of deep reflexes, a positive Babinski sign and continued convulsions are some of the signs of involvement of the central nervous system. Post mortem examination shows numerous small hæmorrhages, but no evidence of softening of the brain tissue; the capillaries are filled with hyaline thrombi. The lungs, spleen, and kidneys are all congested but free from thrombi. Arsenic is said to be responsible for the production of these symptoms. Hæmorrhagic encephalitis, however, commonly occurs in the second stage of syphilis. In a few cases it has occurred after a single injection of arsenicals, but in the majority of cases after the second injection. Examination of the brain may show the presence of arsenic or not. The ætiology or hæmorrhagic encephalitis is probably the same as that of the acute vasoparetic reaction following injection of arsphenamine.

Dermatitis and allied reaction. These are the most annoying of all reactions and consist of rashes on the skin and mucous membranes. They are less common with organic compounds and their characters depend chiefly on the sensitiveness of the patient to the drug, the amount of arsenic given and the degree of skin reaction. The most common types are patches of urticaria, erythema and rarely purpura, sometimes there is only itching. The eruptions generally subside in a day or two. More persistent eruptions occur 6 to 10 days after administration, especially after intravenous injections. The severe type of reaction may turn into exfoliative dermatitis which is very serious, as death follows after its appearance in about 30 per cent. of cases. Various stages may be passed so rapidly that an initial urticaria or discrete erythema may become a confluent erythema in 24 to 48 hours; later it may turn vesicular and subsequently

pass on to exfoliative dermatitis. Arsenicals should therefore be discontinued if signs of skin irritation appear. Kolmer has classified these reactions into 4 groups.

1. Mild and early skin lesions consisting of simple erythematous rashes, urticaria, herpes, pruritus. These may be due partly to colloidal phenomena and partly to liberation of spirochætal endotoxins—Herxheimer's reaction.

2. Severe and late skin lesions consisting of dermatitis and purpura. The former may consist of scarlatiniform erythema with desquamation, erythema multiforme (papular and vesicular), lichen-planoid or with acute exfoliation which may be simple, rheumatic or hæmorrhagic.

3. Mucous membrane lesions consisting of stomatitis, exfoliative ileocolitis, conjunctivitis, vaginitis and broncho-pneumonia.

4. Chronic and recurrent skin lesions such as fixed arsenical rashes, pigmentation and argyria, melanosis, hyperkeratosis of the palms and soles of the feet may develop.

Forms of eruption. 1. *Erythema.* This may vary from mild redness to deep redness with a purple tint. It blanches on pressure, appears first on the flexor surface of the limbs and trunk. It may be petechial or hæmorrhagic, but often it is either morbilliform or scarlatiniform, erysipelatoid or of a patchy character resembling a copaiba rash. The rash may be discrete and papular, though the urticarial form is more common; it may be accompanied by a pemphigoid eruption which is characterised by the formation of vesicles and blebs that leave considerable pigmentation behind.

2. *Exfoliative dermatitis.* This is preceded by an acute erythematous dermatitis and in a mild case it does not go beyond the erythematous stage. The infiltration is more noticeable on hands, feet and ears; vesicles or bullæ may form and rapidly rupture, thus producing areas of acute weeping dermatitis, marked redness of the skin, exfoliation, crusting and scabbing from the drying exudate. The whole body may be uniformly affected or exfoliation may be confined to certain parts especially the ears, scalp, armpits, groins and fold of the skin. There is œdema of the eyelids, conjunctivitis and photophobia. Fever, headache, faucial congestion and emaciation are present. Secondary infection may take place. There may be loss of the hair of the scalp, eyebrows and eyelashes. The main complica-

tions are glandular enlargement, abscess formation in the groins, broncho-pneumonia, cedema of the lungs, exfoliative vaginitis. Albuminuria may be present. When recovery occurs convalescence is protracted, the skin becomes thin and atrophic and assumes a brown tint.

3. *Chronic skin lesions.* Fixed arsenical exanthemata develops by the production of urticarial patches in the same situation leading to an elevated smooth plaques. Raynaud's syndrome with gangrene has been recorded. Fibrosarcoma at the site of injection of arsphenamine has occurred.

Pathology. The skin lesions are due to the direct effect of the arsenical compounds and not due to the syphilis itself, as they have occurred in non-syphilitic patients treated with arsenicals. Recent work by Osborne (1928) has shown that the skins of patients with dermatitis contain more arsenic than those without. It has been shown by micro-chemical methods that arsenic is deposited deep in the corium around the arterioles and capillaries, in the walls and lumens of the sweat and sebaceous glands, in their ducts and in the hair follicles and hair shafts. The arsenic is always extra-cellular and the amount present is proportional to the severity of the dermatitis. Pentavalent arsenic appears to have a special affinity for ectodermal structures, *e.g.*, the epidermis, sweat and sebaceous glands, hair, and relatively little affinity for blood vessels of the corium. Pentavalent arsenicals therefore produce mild dermatitis, keratosis, pigmentation, wrist drop and optic atrophy; while trivalent compounds cause severe dermatitis, encephalitis and purpura. The incidence of severe skin reactions is 1 in every 500 to 1,000 injections and sulpharsphenamine produces a somewhat higher incidence. Non-syphilitics may also develop it. The skin reactions are 2 to 3 times commoner in white races than in coloured races.

Post-arsphenamine dermatitis is now considered to be the result of direct sensitization to arsphenamine, to the products of its metabolism or to a state of general allergic instability or to a hypersensitiveness not necessarily absolutely specific for arsphenamine. Two theories have been advanced to explain this condition. The hepatotoxic explanation holds that the liver is damaged to the extent that it is unable to detoxicate arsphenamine when introduced or else causes an altered metabolism of the arsphenamine. Jaundice seems to be a very common accompaniment. Liver extract has been used in arsenical dermatitis with good results, and sodium-dihydrocholate sometimes prevents hepatic reactions or post-arsphenamine jaundice. These facts show the possible relationship. The second theory known as epidermovasculotoxic or vasoneurotic theory, accounts for the cutaneous reaction as a primary toxic effect on the involuntary or autonomic nervous system which causes excessive

loading of arsenic in the skin, and liver. ~~The circulatory system, particularly liver.~~ The circulatory system, particularly the walls of the blood vessels form the chief point of attack.

Treatment. Most cases of arsphenamine dermatitis present warning signs before the generalised dermatitis begins. In early cases, the treatment with arsphenamine should be guardedly continued by changing to a different type of arsenical, smaller doses, etc., before true allergic state develops. Physiologic solutions of sodium chloride, dextrose, gelatin, sodium thiosulphate and calcium have been added to the arsphenamine to render it less toxic. Clinical experience has proved that sodium thiosulphate is a very valuable detoxicating agent. Its mode of action is unknown but probably it transforms arsenic into a less toxic, less efficient and a less easily excretable product. On the other hand, some authorities believe that owing to the presence of the sulphydryl group, sodium thiosulphate changes the insoluble arsenic compounds developed in the skin into soluble forms. In order to avoid arsenical dermatitis it is advisable to combine sodium thiosulphate with arsphenamine. But once the dermatitis has set in, sodium thiosulphate fails to hasten the resolution; its value only lies in its use early in the disease. Fifteen grains (1.0 gm.) of sodium thiosulphate by the mouth 3 or 4 times a day is said to produce good results, but in severe cases it should be given intravenously in 10 per cent solution, starting with 0.3 gm. on the first day, then 0.45, 0.6, 0.9, 1.2 and 1.8 gm. on successive days. At the same time it is given by the mouth in 2 gm. doses twice daily in 120 to 200 c.cm. of normal saline. Thiosulphate is said to act by releasing the arsenic deposited in the skin and along the nerve trunks until gradual return to normal is observed. The excretion of arsenic is accelerated, the parchment-like condition of the skin disappears and the pigmented areas become normal. Beinhaner and Jacob (1928) are of opinion that Wassermann-fast syphilis is due in some cases to a saturation of the tissues by the heavy metals used in the treatment, or to arsenic-fast or mercury-fast strains of spirochaetes. In such cases sodium thiosulphate produces excellent results. They recommend a series of bi-weekly intravenous injections for 5 to 7 weeks, an average dose of

0.6 gm. of the drug being given at each injection. The patient also receives 15 grains (1.0 gm.) of this drug daily by the mouth at the same time. Sodium thiosulphate definitely alters the serum reaction in some cases of Wassermann-fast syphilis.

Thiosinamin has also been recommended intravenously in 3 grain doses in 10 c.cm. of sterile water but it may produce digestive disturbances, lassitude and fever. Intramuscular injections of intramine in doses of 2.5 c.cm. of a 1.0 per cent. emulsion are beneficial; as many as 12 injections may be given.

Liver therapy. Based upon the hepatotoxic theory, some workers have used injections of liver extract in the treatment of arsenical dermatitis with good results. It is given in doses of 5 to 10 c.cm. intramuscularly, three times a week. The therapy stimulates the disturbed function of the liver, cures chronic arsphenamine intoxication and prevents further manifestation of arsphenamine sensitisation.

Other effects. An intense necrotic type of enteritis has followed treatment with arsenicals and mercury, leading to perforation and fatal peritonitis. Severe parenchymatous degeneration of the kidneys has been known to occur after arsphenamine. A true syphilitic nephritis is well known. Arsphenamine in rare cases may produce aplastic anæmia with degeneration of the bone marrow. There may be bleeding from the gums and mucous membranes in many cases and the red cell count may be reduced to 80,000 and hæmoglobin to 13 per cent., the leucocyte count is also reduced. Post-mortem examination shows complete aplasia of the bone marrow and broncho-pneumonia with a poor cellular reaction.

Syphilitic and arsenical jaundice. The intensity of jaundice may vary from a transitory jaundice to acute yellow atrophy of the liver. It may be early or benign, late or severe, and lastly acute yellow atrophy may result. Early jaundice commences within a few days, sometimes within a few hours of the injection. It may come on after the first injection or after any subsequent injections. There may or may not be any constitutional disturbance, but that does not mean that the liver has not been damaged. Cases have been recorded with initial transient jaundice but some months later the patient has died of acute yellow atrophy of liver. Late jaundice is a very serious condition. It is accompanied by fever and usually occurs after many

injections (one or two courses) and is believed to be more commonly caused by neo-salvarsan, though there are no data to support this belief. Jaundice is generally intense and unless there is acute yellow atrophy of the liver, the patient may recover. In the late type of jaundice symptoms are not so severe as in acute yellow atrophy. The jaundice, from the beginning, is intense but non-febrile. Then suddenly symptoms of acute hepatic insufficiency, such as fever, rigors, vomiting, delirium and other nervous symptoms supervene and the patient dies of coma. Kolmer has classified jaundice into four groups according to its ætiology.

1. Due to arsenic, by production of fatty degeneration, hepatitis or obstructive jaundice produced by gastro-enteritis. That the arsenicals damage the liver can be shown by the lævulose and blood lipase test, even therapeutic doses produce structural alterations, and the phenol-tetrachlor-phthalein test shows signs of insufficiency after a series of doses or courses. The interesting fact in connection with acute yellow atrophy is the long latent period usually intervening between the last injection and the onset of symptoms. With trinitrotoluene, jaundice may occur 2 to 10 months after exposure. It has been suggested that this delay is due to the fact that arsenic is stored partially in the body. If for any reason these depots are rapidly depleted, a large amount of arsenic is liberated and the liver is attacked.

2. Due to syphilis alone. This may be mild or severe and the pathological changes are perilepatitis, diffuse hepatitis or gumma.

3. Due to arsenic and syphilis. This is considered to be a form of Herxheimer's reaction; syphilitic infection of the liver is intensified as a result of administration of arsenicals. Arsenicals may also stimulate a bacterial infection of the liver.

4. The immediate predisposition to jaundice is neither due to arsenic nor syphilis of liver, but in the majority of cases to summation of the changes produced by the disease and the arsenicals, and it is possible that the administration of mercury may help in intensifying the hepatic damage. Jaundice is the result of combined hepatic disturbances and cholangitis produced by syphilis and arsenic, while in other cases it may be due to Herxheimer's reaction when latent spirochætes in that organ have been stimulated into renewed activity. Experiments on dogs have shown that with chloroform the amount of damage produced in the liver is variable, but if living bacteria are injected at the same time all grades of hepatic damage from acute atrophy to cirrhosis may occur. Other infections such as Weil's disease (*Sp. icterohæmorrhagica*) may be etiological factors. Liver function tests such as the phenol-tetrachlor-phthalein test are useful, as syphilitic

hepatitis is not usually suspected till jaundice and the accompanying symptoms appear.

Treatment of jaundice. Rest in bed, mild laxatives, carbohydrate diet which increases the resistance of the liver, with no fats and little proteins are recommended. Milk may be given and the patient is advised to drink plenty of water. When jaundice is clearly due to syphilis, give anti-syphilitic treatment with arsenicals, mercury or bismuth compounds; but if due to arsenic injections these should be immediately stopped. Intravenous injections of sodium thiosulphate, thiosinamine or con-tramine (diethyl-ammonium diethyl-dithiocarbamate) have been recommended.

Many fatalities attributed to arsenicals are really due to advanced pathological changes produced in the internal organs by the disease in which these drugs either should not have been given at all or only in very small doses. Women are more likely to develop reactions than men. Mild reactions such as nausea, headache, fever, diarrhoea, etc., are more common among them; the incidence of jaundice is also higher. Severe and fatal reactions are more common among men; children are more tolerant to arsenicals. The incidence of reaction according to Kolmer (1926) is generally higher after 5 or more injections than after the first injection. There is also a greater tendency to reaction during the second or subsequent courses. It is probable therefore that the effects are due to the accumulation of arsenic in the liver and other organs, to the production of tissue injury or to interference with the metabolism or excretion of these compounds. In some cases an allergic sensitiveness is acquired for the drugs.

Meirowsky (1920) showed that when the dose of neo-salvarsan exceeded 0.6 gm. the death rate went up considerably and hence he recommended 0.6 gm. to be the maximum dose. The death rate was much less with neo-salvarsan than with salvarsan. Strong solutions of salvarsan and sulfarsenol are directly hæmolytic *in vitro* for washed corpuscles, but they are much less so in the presence of serum, and intravascular hæmolysis is not therefore very likely to occur. Weak solutions of salvarsan such as 1 in 5,000 are said to have an antihæmolytic effect. Concentrated solutions, especially if injected rapidly, produce fatal results. Neo-arsphenamine has little hæmolytic action unless dissolved in water. Atoxyl, tryparsamide and other arsenicals are less hæmolytic in saline solutions and only slightly hæmolytic in water. It will thus be seen that hæmolysis can to a certain extent be prevented. The susceptibility of the erythrocytes to hæmolytins differs in different individuals and even a small amount of hæmolysis may produce symptoms resembling protein shock.

Nervous reactions. Numbness of the fingers and the soles of the feet may occur. As these symptoms frequently forecast the onset of dermatitis the injections should be stopped. As a rule these are not accompanied by pain but this may occur and polyneuritis may be produced followed by paralysis. Neoarsphenamine is said to have produced more cases of paralysis than arsphenamine. Sometimes injections are followed several weeks or months later, by severe nervous manifestations, *e.g.*, epileptiform convulsions. They occur also with mercury and Ehrlich suggested that they are due to incomplete destruction of the parasites. The optic and auditory nerves are not affected by trivalent compounds but atoxyl and tryparsamide (pentavalent compounds) produce retrobulbar neuritis and transient dimness of vision or amblyopia. Young and Lævenhart (1924) showed that arsenicals with an amino group or a substituted amino group in the para position to the arsenic, *e.g.*, atoxyl, produce optic atrophy in the rabbit. Organic arsenicals with the amino group in the ortho or meta position to the arsenic on the other hand, produce no optic atrophy. Herxheimer's reaction occurs in secondary syphilis especially if large doses have been given; small ascending doses of these compounds do not produce it.

Summary. The toxic symptoms produced by injections of organic arsenicals may be briefly classified as follows:—(1) Those occurring immediately, *e.g.*, flushing of the face, headache, lachrymation, oedema, dyspnoea, swelling of the lips, tongue and eyelids, nausea, vomiting and retching, unconsciousness and very rarely death (anaphylactoid or nitritoid crises). (2) Those appearing within 24 hours, *e.g.*, chilliness, rigors, headache, vertigo, diarrhoea, and rise of temperature. (3) Those observed after 24 hours, *e.g.*, epileptiform convulsions, dilation of the pupils, loss of reflexes, coma and rarely death. In addition there may be eruptions on the skin, exfoliative dermatitis (complicated with broncho-pneumonia and septicæmia), jaundice (early, late and acute yellow atrophy), epilepsy or hæmorrhagic encephalitis. Acute yellow atrophy often supervenes on late jaundice. Rare lesions are acute hæmorrhagic nephritis, ulcerative enteritis and aplastic pneumonia. (4) Complications now regarded as relapses of syphilis, are due to

spirochaetal toxins suddenly liberated. These include affections of the nervous system, deafness, cranial nerve palsies, etc.

Pathological changes produced by organic arsenicals. These changes were studied in animals. The type of changes produced is the same with all the trivalent and pentavalent compounds, some being more toxic than others. Tissue changes are chiefly due to the arsenic constituent and consist of, (1) congestion of capillaries and consequent serous exudation and minute hæmorrhages and (2) parenchymatous degeneration of organs and necrosis. If death occurs at once or within a few hours, there is widespread intense hyperæmia of the brain and meninges, lungs, liver, kidneys and other organs, with extensive thrombosis and plasma precipitates. Small capillary hæmorrhages are found in some organs, but degenerative lesions are not produced unless the animals survive a few days. In human subjects, where death occurs within 24 hours after accidental administration of acid solution of salvarsan, advanced degenerative lesions are found in the liver, kidneys and other organs. The majority of deaths in human subjects have occurred after several doses have been given, death being due to chronic rather than acute poisoning. In Europe, salvarsan fatalities are mostly ascribed to hæmorrhagic encephalitis but in the United States they have been put down to degenerative changes in the liver and kidneys.

In rats irregularly distributed areas of degenerative changes with lymphatic infiltrations are found in the myocardium after 10 or more small doses. Such changes in the human heart therefore should not be attributed to syphilis. Vascular lesions are especially marked in the lungs. After a single dose, when examined two days after the injection, marked congestion, small thrombi of coagulated erythrocytes are seen with areas of scattered congestion and extravasation of red corpuscles in the air sacs. After injection of numerous small doses the capillaries are found to be tortuous and densely packed with erythrocytes. The walls of the air sacs are thickened, the whole picture suggesting passing congestion and capillary oedema; there are no pleural changes.

The changes produced in the liver are of interest specially in relation to jaundice. A single large dose in rats produces extensive areas of coagulation necrosis involving all parts of the lobule, particularly the middle and the central portions. Rats succumbing after 2 days show the same changes as in acute yellow atrophy. After 10 or more small doses peripheral fibrosis with small areas of focal necrosis is noticed. The kidneys after a single large dose show congestion of the cortex, minute interstitial hæmorrhages and cloudy swelling, especially of the convoluted tubules. After repeated small doses the kidney changes are not marked. Clinically it has been noticed that kidney changes are less likely to occur with arsenicals than with mercury and bismuth compounds. In the supra-renals, after a large single dose, great reduction in the lipid and chromafin contents is produced. In the spleen large single

doses produce areas of coagulation necrosis while small doses produce no marked changes. Kolmer and others (1922) found no decrease in the adrenalin content of the suprarenal glands after injection of arsphenamine in therapeutic doses.

It will be seen from the above that repeated injections of small doses are much less toxic than single large dose, and the small changes that are produced in the organs are quickly made good. It is likely that 'nitritoid crises' are due primarily to the direct action of arsenic on the capillaries in individuals hypersensitive to arsenic. The skin eruptions such as urticaria, and exfoliative dermatitis, may be due to the direct action of arsenic on the capillaries and excretory glands of the skin, while jaundice is ascribed to necrosis of the liver cells by arsenic or to a phenomenon resembling Herxheimer's reaction. The susceptibility of the individual is a very important factor and so also are the pre-existing pathological changes produced by disease. For this reason, treatment of chronic syphilitics with organic arsenicals presents a much more difficult problem than cases of early syphilis.

Cautions and contra-indications. The only real contra-indication is hypersensitiveness to arsenic. Individuals who develop acute reactions, dermatitis and jaundice are bad risks and in these cases other drugs should be tried. Sometimes the substitution of one compound for another may avert such reactions. In minor cases of dermatitis if a beginning is made with a small dose and it is gradually increased, severe reactions may be avoided. A sharp look-out must be kept for urticaria, fleeting erythema, itching of the palms, etc., as these give a warning that more severe reactions may follow. Cases of jaundice are also bad risks and very great care should be taken in giving arsenicals if previous injections have caused it.

Organic arsenicals should be given with caution in cases of emaciation, malnutrition, in diseases of the heart and blood vessels (syphilitic aortitis and myocarditis), in tuberculosis with hæmoptysis, in affections of the brain and meninges, in advanced cases of diabetes and nephritis, and in old and feeble persons of very advanced age. Arsenic should not be given where vitality is very low as a result of acute manifestations of syphilis. In syphilis of the optic nerve pentavalent arsenicals should never be given, while trivalent compounds should only be tried in small and ascending doses. According to some authorities tryparsamide may be given safely when the optic

nerve is diseased provided the doses are small and carefully regulated.

Prophylaxis of toxic reactions. The measures taken have been divided into three groups.

1. *Those referable to the patient.* Allay fear and nervousness; if constipation is present it should be relieved; the injection should be given on an empty stomach, preferably in the morning; the urine should be examined previously in all cases, especially when mercury and bismuth are also being tried; the functional capacity of the liver may be tested in selected cases. The first dose should be small, $\frac{1}{4}$ to $\frac{1}{2}$ of the usual dose; this tends to increase the tolerance of the individual. In long-standing cases, give mercury or bismuth first or very small doses of arsenicals to prevent Herxheimer's reactions. In women the injections should not be given during the menstrual period and special care should be exercised when pregnancy exists, as abortion may take place. When giving pentavalent compounds special attention should be paid to the eyes to guard against toxic amblyopia. The injections should be given deep into the muscles and not into the fatty tissue. In patients likely to develop vaso-paretic symptoms 1/100 to 1/50 grain of atropine sulphate should be given half-an hour before the main injection. Two to 8 minims of 1 in 1,000 adrenalin intramuscularly before the injection prevents acute vaso-paretic reactions. Adrenalin is the most useful drug to cope with 'nitritoid crisis.' Injection of calcium salts either prior to or in conjunction with salvarsan or neo-salvarsan injections is said to prevent the toxic effects of the drug. Calcium chloride dissolved in distilled water is usually given intravenously, but it may also be administered orally.

2. *Those referable to the preparation and administration of solutions.* Use freshly distilled water or saline free from organic matter. For dilute solutions (50 c.cm. or more) use 0.5 per cent. saline in preference to water. Filter all solutions. After neutralisation allow arsphenamine solutions to stand for 10 to 20 minutes before injection. Injections should be given slowly. New rubber tubing should be avoided.

3. *Those referable to the drug.* Avoid products over two years old and all cracked ampules should be thrown away.

If there is suspicion of a crack dip the ampoule in alcohol which will find its way in if there is a leak. Before injection carefully verify the drug which is going to be injected. Solutions should never be given unless they are brilliantly clear; cloudy solutions produce abdominal pains and immediate syncope. If necessary they should be filtered.

Keeping properties and media for solution. Salvarsan and the allied compounds should be kept sealed in ampoules in vacuo. It is better to use fresh rather than old specimens. Solutions of the compounds can be kept for six months or longer without physical changes or increase of toxicity if the oxygen is rigidly excluded. The Hygienic Laboratory of U.S.A. has placed a limit of six months on them from the date of preparation. Freshly distilled water should be used for making solutions. When concentrated solutions of neo-salvarsan are employed they should be dissolved in distilled water, but if dilute solutions of salvarsan are used the drug should be dissolved in 0.5 per cent. saline solution prepared from chemically pure sodium chloride. A 5 per cent. solution of glucose as a medium for dissolving these compounds reduces the toxicity by preventing oxidation in solution, at the same time it does not reduce their therapeutic activity. In 0.5 to 2 per cent. gelatine solution the toxicity of these compounds is said to be reduced, but as this gives rise to reactions such as malaise, chilliness, etc., it is not recommended. Solutions of salvarsan in water heated up to 60° to 70°C and then cooled do not show any increase in toxicity; neo-salvarsan and sulfarsenol are best dissolved in cold water. It has been clearly established by experiments that it is better to use dilute solutions of salvarsan (0.4 gm. in 20 to 25 c.cm.) while concentrated solutions (0.9 gm. in 2 c.cm.) of neo-salvarsan and sulfarsenol do not do any harm when given intravenously. It has been pointed out that shaking the solution in air, even for a few seconds, increases the toxicity of all these compounds by oxidation to arsenoxide, but if contact with air is prevented by means of stoppered bottles, solutions may be safely kept for a few hours before injection; some say they may be safely kept for 24 to 48 hours. Excess of alkalinity or acidity of the salvarsan solution are both dangerous.

CHAPTER XXXI

BISMUTH AND ITS DERIVATIVES

Bismuth compounds were used as cicatrising agents in the treatment of cutaneous lesions as early as the 17th century, and towards the end of the 18th century they were given internally for gastro-intestinal disturbances; bismuth oxide was used for dressing wounds and ulcers. Balzar (1889) carried out a series of experiments on dogs to test the toxicity of bismuth compounds with a view to their employment in syphilis. He first successfully tried bismuth ammonium citrate in human syphilis. Robert and Sauton (1916) tried bismuth preparations in the treatment of spirochaetosis of fowls and found them to be very efficacious. Kolle and Ritz (1918) injected colloidal bismuth intravenously in syphilitic rabbits with beneficial results, but did not pursue the subject further. Sazerac and Levaditi (1921) carried out systematic research in the subject and found that in experimental syphilis of rabbits bismuth compounds had a well-marked curative action. They tried intramuscular injections of tartro-bismuthate of sodium and potassium (trepol) in syphilis in man and found that though the injections were painful, the drug produced rapid cicatrization of the lesions of this disease. Further trials by Fournier and Guenot (1922) showed that primary chancres healed rapidly, secondary lesions were inhibited and early secondary and tertiary lesions disappeared after 10 to 12 intramuscular injections of bismuth. In trypanosome infections the action was not marked.

These findings led gradually to the introduction of bismuth in the treatment of syphilis. As an adjunct to the arseno-benzene derivatives, bismuth is now recognised as a drug of considerable value and has replaced mercury in the chemotherapy of syphilis. It will therefore be of interest to consider the subject in detail, with special reference to the new contributions that have been made in connection with its pharmacological action and toxicological properties.

Pharmacological action. Like arsenic and antimony, bismuth in very high dilutions exerts a markedly toxic action on certain pathogenic protozoa; 1 in 200,000 will kill some of the organisms *in vitro* and it is possible that in the body this action may take place even in lower concentrations. Like atoxyl, these compounds only become active when incubated with liver extract and to a lesser extent with extracts of other tissues. The bactericidal properties of bismuth compounds have not been thoroughly studied, but their action in checking undesirable fermentation in beer worts was known long ago. Common bismuth salts like the subnitrate and the subgallate, etc., are decomposed by water to a greater or lesser extent, and can exert a mild but effective and prolonged antiseptic action.

External. Soluble bismuth salts are not used externally. The insoluble basic bismuth salts are largely used as dusting powders on inflamed surfaces. Their action is mainly mechanical as protective, drying and dusting powders. Applied to wounds, they dry secretions and form a protective covering so that the wound heals under an aseptic scab. A small amount of bismuth goes into solution and acts by exerting an astringent and antiseptic action. Sometimes absorption from the wounds and raw surfaces may be very rapid giving rise to symptoms of poisoning.

When applied to the unbroken skin in the form of inunctions, bismuth does not exhibit any curative action in syphilis. Cutaneous syphilitic lesions are not affected by the local application of bismuth.

Internal. Bismuth compounds have the reputation of being antacids. This effect is partly due to diminution of gastric secretion and partly to neutralisation of the gastric acidity. So far as the subnitrate is concerned this is undesirable as it does not fix the free acids to any great extent in the stomach. In the intestines both the subnitrate and the subcarbonate neutralise the sulphides of alkali metals and hydrogen sulphide, which produce irritation and increased intestinal peristalsis; these bismuth salts thus act as gastro-intestinal sedatives in inflammatory conditions of the gut. Further they coat the surface of the inflamed mucous membrane and allay irritation by preventing the irritant gases and fluids from coming in contact with the mucosa. They also exert a certain amount of antiseptic and astringent effect and are therefore prescribed in diarrhoea. Basic salts of bismuth are among the most effective of the non-irritant intestinal antiseptics. Subcarbonate of bismuth is preferred to subnitrate as the latter is converted into nitrous acid by reduction in the intestines. The use of soluble bismuth salts in irritative conditions of the gastro-intestinal tract is irrational since they are absorbed more readily and lack the soothing qualities of the insoluble preparations. In the gut bismuth salts are converted into sulphide, which is black in colour; it may form crystals looking like hæmatin and may be mistaken for it.

Circulation and respiration. After intravenous injections, even in small doses, there is a fall of blood pressure, partly due to depression of the vasomotor centre, but chiefly to the direct effect on the heart which becomes slow and irregular. The respiration is accelerated at first, but later depressed. The blood shows a mild and temporary leucocytosis after injections of bismuth salts. Neutrophiles and eosinophiles are increased at first, followed by an increase of lymphocytes. In some cases erythrocytes are increased while in others there is destruction of the red corpuscles. Punctate basophilia may occasionally occur. These effects appear to be due to the action of bismuth on the bone marrow which is stimulated temporarily by small doses, while in large doses toxic effects are produced.

Kidneys. All bismuth compounds tend to increase the output of urine and thus promote their own excretion. The administration of water and sodium chloride, etc., hastens the excretion of bismuth. A high chloride dietary would, therefore, favour the efficiency of bismuth medication by helping the mobilisation of the metal from the tissues. The diuretic action of bismuth may be made use of in the treatment of œdema and anasarca. Its action has been found to be well sustained and useful in the removal of large quantities of fluid.

Central nervous system. In frogs the symptoms are those of stimulation of the spinal cord and medulla oblongata, followed by depression and paralysis. In mammals, intravenous injections of large doses of bismuth act chiefly on the central nervous system producing violent clonic and tonic convulsions, followed by short intervals during which the movements are weak and inco-ordinated.

Absorption of bismuth. Only very minute quantities of bismuth are absorbed from the alimentary canal. This is shown by the fact that poisoning never results even when large doses of bismuth compounds are given by the mouth if the mucous membrane is intact. If there is solution of continuity and ulcers are present, the drug may be rapidly absorbed.

Absorption is so slow and uncertain from the gastro-intestinal tract that this route of administration is not employed for the treatment of such diseases as syphilis where a systemic action is desired. Absorption of bismuth from the skin in any form is not demonstrable as in the case of mercury. Hypodermic injections are too irritant and are not advisable. Intravenous injections of most of the bismuth compounds are not considered safe. This can be judged from the fact that while intramuscularly a rabbit can survive 200 mgm. of bismuth salts per kilo. body weight, 5 mgm. is sufficient to kill it if given intravenously. Intramuscular injection is therefore the only mode of administration and is universally adopted.

All bismuth products are tissue-soluble though in varying degrees. Absorption from the site of injection starts promptly but does not go on at the same rate in every case. This has been studied carefully by chemical, roentgenological and histological methods in animals, and also clinically in human beings. Saturation of the body with bismuth is more rapid, uniform and satisfactory with the soluble than with the insoluble salts. Absorption of the drug has been found to depend on several factors:—(a) the solubility of the original compound, (b) the site of the injections, (c) the number and frequency of the injections and (d) the dosage of bismuth employed. The solubility of the compound appears to play a most important part in absorption. Sollmann has grouped the bismuth preparations according to the degree of their solubility in different vehicles, as follows:—

Group I. Those soluble in water and in water-miscible media such as sucrose solution and ethylene diglycol. Water-soluble compounds suitable for this purpose are the double salts, sodium or potassium citrate or tartrate; sodium iodo-bismutite (iodobismutol) and sodium bismuth thioglycollate (thiobismol).

Group II. Those soluble in oil, including basic bismuth salts of certain organic acids (biliposol, cymbismol) and quiniobin, an oil-lecithin solution of bismuth-iodoquininate.

Group III. Oil suspensions of water-soluble compounds, especially the potassium bismuth tartrate

Group IV. Oil suspensions of insoluble (or sparingly soluble) compounds, such as bismuth iodoquininate (quinby), salicylate (subsaliolate), benzoate and oleate and metallic bismuth.

Group V. Watery suspensions of insoluble compounds, such as bismuth hydroxide (Lomholt's magma), metallic bismuth (neotrepol), and semicollodial bismuth (bismol).

The first group of bismuth compounds is most easily absorbed, though some compounds of this group tend to get precipitated by interaction with the tissue fluids at the site of the injection. Oily solutions cannot come intimately in contact with the tissues, produce much less irritation locally, and are apt to get encapsulated before absorption is completed. Hence they are not absorbed so well as the watery solutions but the process of absorption goes on for a long time and is obviously advantageous when prolonged effect is sought.

Fate of bismuth in the body. After absorption, bismuth like antimony, is widely distributed in the tissues of the body but in unequal amounts. After intramuscular injections bismuth can be detected in the blood in fairly high concentration in the plasma, though the corpuscles also contain it in negligible amounts. The concentration is highest in the kidneys indicating that the kidneys can store bismuth. The long bones, liver, lungs, spleen, skeletal muscles and the brain also contain traces of the drug. The placenta is permeable to bismuth and it can be

found in the foetus. Demelin (1922) was able to detect bismuth in the cerebro-spinal fluid of patients treated with intramuscular injections of 0.2 gm. of 'trepol,' but Jeanselme and his co-workers (1924) with a delicate method, capable of detecting bismuth in 1 in 1,000,000 dilution, failed to detect it in 31 patients who had intravenous injections of bismuth. There is no doubt however that there is improvement in the condition of many neuro-syphilitics following bismuth injections and minute quantities probably reach the central nervous system.

Bismuth appears to have the same distribution as other heavy metals, such as mercury and lead and is chiefly found in the organs concerned in its elimination. Owing to its widespread distribution syphilitic lesions of different parts of the body improve after bismuth therapy.

Excretion. Although some bismuth is stored in the liver and other organs, the greater part is eliminated by the kidneys, liver and intestines, only traces occur in sweat, milk and tears. The main channel of excretion appears to be the kidney, only one-twelfth to one-eighth of the bismuth appears in the faeces. Bismuth appears in the urine within 18 to 24 hours after intramuscular injection of 'trepol' and excretion is continued for 20 to 25 days after a course of treatment in which 2.0 to 2.5 gm. of this substance have been injected. After intravenous injections, bismuth can be detected in the urine in four hours. Sometimes the urine when voided is discoloured or becomes so on standing. In the latter case this is due to the formation of bismuth sulphide by the action of bacteria. The diuretic action of bismuth salts has already been referred to.

In human poisoning, bismuth is found mainly in the stomach and kidneys, and a little in the liver. Autopsy shows the caecum, adjoining colon and appendix stained black with bismuth sulphide, which is deposited on the mucous membrane in the capillary vessels and lymph spaces. The small intestines are clear.

CHAPTER XXXII

THERAPEUTIC USES OF BISMUTH

Bismuth subnitrate and carbonate are valuable drugs in the treatment of inflammatory conditions of the intestines, in diarrhoeas and in gastro-duodenal ulcers. They should be given in large doses, 30 gr. (2.0 gm.), as a powder or in suspension, by itself or in association with magnesium oxide or sodium bicarbonate on an empty stomach. Bismuth compounds act well in gastralgia and hyperchlorhydria. Bismuth subcarbonate or salicylate in 5 to 10 gr. dose several times a day in gelatine capsules is very useful in combating flatulence. In combination with alkalis they are also used as accessories to the emetine treatment of amoebic dysentery. They also ameliorate symptoms of this disease by their inhibiting action on the peristaltic movements of the intestine by neutralising the alkaline sulphides and sulphuretted hydrogen present there. They are used in chronic ulcers of the skin and in the treatment of deep-seated sinuses. The nitrate or carbonate of bismuth, mixed with vaseline in 30 per cent. strength is injected into tuberculous and other sinuses with the object of producing healing effects by cicatrization. They are however liable to cause poisoning if the sinuses are very extensive.

Syphilis. The bismuth treatment of syphilis is one of the noteworthy recent advances of therapeutics. The spirochæticidal properties of the organic and inorganic compounds of bismuth have been thoroughly tested and they are being largely used at present in the treatment of syphilis, especially by the French physicians. Robert and Sauton (1916) found that in spirochaetosis of fowls (*S. gallinarum*) doses of 0.2 to 0.03 gm. per kilo. intravenously or intramuscularly had a markedly beneficial effect. Doses of 0.005 to 0.015 gm. intravenously and 0.06 to 0.07 gm. intramuscularly injected 6 hours after infection invariably cured the animals. Similar results were obtained by Sazerac and Levaditi (1921) in experimental syphilis in rabbits, and by Fournier and Guenot (1924) in man. Bismuth

compounds such as 'trepol' are found to possess spirochæticidal activity of a very high order. This will be appreciated from the fact that a concentration of 0.2 mgm. in one litre of blood is sufficient to produce an antisymphilitic effect. A single therapeutic dose is five times smaller than the single maximum tolerated or toxic dose, i.e., the chemotherapeutic index is 5, which is very much higher than that of mercury compounds, but not so high as that of the organic arsenicals.

All forms of clinical manifestations of syphilis respond to bismuth treatment. The effective curative dose is 4 to 5 mgm. per kilo. per course of two or three courses. In primary and secondary syphilis a few centigrammes of 'trepol' produce rapid disappearance of spirochætes from the lesion, and cicatrization. Spirochætes disappear from the chancre in 24 to 56 hours, the chancre is healed in 4 to 10 days, and enlarged lymph glands in the neighbourhood of the chancre disappear. Rapid disappearance of mucous patches occurs after administration of bismuth compounds; a previously positive Wassermann reaction may become negative under treatment but not so rapidly as with the arsenicals. With colloidal bismuth mucous papules become cicatrized and treponema disappear after the first or second injection. Headache, fatigue and pains in the bones frequently cease after a few injections. In the tertiary stage of the disease bismuth is also useful, gummata disappear and also chronic encrusted ulcers of long standing and ulcers of the palate heal up rapidly. Cases which are resistant to mercury and arsenic, sometimes do better with bismuth. According to Meyer and Corbett (1923) bismuth appears to be less effective and slower in action than salvarsan but more effective than mercury. After treatment with arsphenamine no living spirochætes can be detected after 24 hours, whereas after treatment with bismuth, living spirochætes do not disappear for 3 to 4 days in the mucous lesions. Levaditi and Fournier (1928), however, state that liposoluble bismuth preparations act as rapidly as the arsenicals in destroying spirochætes. Bismuth has definite advantages over mercury and arsenic in some respects. It is not so depressing as mercury, old and debilitated patients tolerate it better than arsenic, and it can also be given for a much

longer period than either mercury or arsenic. Bismuth is specially effective in syphilitic lesions of the eye. In congenital syphilis the action of bismuth is more marked; although it is not so rapid as the arsenicals, it is more certain. That reinfection after bismuth therapy has occurred shows that the sterilization produced by it is definite and permanent. Simultaneous treatment with arsphenamine is not necessary for clearing and healing of acute lesions, or for sterilisation of lymph glands, as bismuth is effective by itself. Combined treatment however is desirable to cut short the length of treatment and to diminish the discomfort and inconvenience of the patients. The combination of bismuth with arsenicals is preferred by many authorities to the combination of mercury and arsenicals because the former is more effective. The usual course in man is $1\frac{1}{2}$ to 3 gr. (0.1 to 0.2 gm.) of sodium potassium tartro-bismuthate or potassium tartro-bismuthate in sterile olive oil or almond oil, weekly or biweekly, until 30 to 40 gr. (2 to 3 gm.) have been given. A six weeks' course of bismuth is followed immediately by a course of arsenicals, followed by a few months' rest. The courses of bismuth and arsenic are again repeated, the progress of the patient being carefully watched with serological tests. Harrison (1929) however thinks that there is no definite evidence of the superiority of bismuth over mercury and that either of the two metals may be used to supplement the arsenic treatment of syphilis.

Effect on serological reactions. The development of a positive reaction in case of primary sero-negative syphilis treated with arsenicals is very rare; but with bismuth treatment a weakly-positive reaction may develop. After one month's treatment of primary and secondary sero-positive cases more sero-negative cases are obtained with arsenicals than with bismuth preparations. Cases of positive Wassermann reaction, which are uninfluenced by arsenic or mercury, are unaffected by bismuth also. In congenital syphilis there is more chance of the reaction becoming negative with bismuth than with arsenicals. The action of bismuth is considered by some to be inhibitory rather than curative.

Neurosyphilis. Syphilis of the nervous system is not frequently benefited by arsenic preparations; in these cases bismuth preparations are useful. Their efficiency in the neuro-manifestations appears to be superior to that of the arsphenamines and equally as good as that of mercury. Tabetics are generally benefited by bismuth compounds, symptoms of gastric crisis and urinary incontinence may be ameliorated and ataxia may show some improvement. Insoluble preparations in the form of intramuscular injections are recommended in these cases, especially when mercury is not well borne. Bismuth is proving more useful than mercury in the treatment of meningeal neurosyphilis with headache. Mercury was the chief drug used in the treatment of neurosyphilis and even now it is advised by the neurologists in combination with arsenical treatment. The reason why mercury fails in general paralysis of the insane is not known but probably it does not penetrate into the nervous tissues. Even bismuth compounds often do not produce much improvement in this condition.

Kolmer has summed up the position of bismuth in the treatment of syphilis as follows:—"Bismuth has established for itself a permanent place in the treatment of syphilis by reason of its low toxicity for the body associated with marked spirochaeticidal properties; it is specially indicated in the treatment of acute syphilis when arsphenamine and its substitutes and mercury cannot be given, *e.g.*, in nephritis, jaundice, etc.; it is of value in the treatment of chronic syphilis and especially that of the central nervous system; it is usually well borne where mercury is not, and therefore serves as a valuable substitute for mercury in chronic syphilis when the latter cannot be given in adequate dosage. Otherwise it is unwise to use it as a substitute for either arsphenamine or allied compounds of mercury, until we know more of its final results. It is worthy of use in the treatment of syphilis in all its stages along with organic arsenicals and mercury, as a form of combination therapy, which is the keynote of success in the treatment of either acute or chronic syphilis. It is specially indicated in cases resistant or intolerant to arsenic."

Prophylactic effects of bismuth in syphilis. The value of mercuric chloride solutions applied locally after exposure to infection has been known for a long time. Experiments on apes and man have shown that inunction with calomel cream prevents development of the infection. In rabbits calomel in lanoline, vaseline, benzoated lard or wax base, proves efficacious up to eight hours after inoculation.

Stovarsol is known to protect monkeys from syphilitic infections for 2 to 7 days.

Bismuth, like mercury and arsenic, is also claimed to have a prophylactic value against syphilitic infections. It has been seen that in experimental syphilis bismuth acts definitely as a prophylactic and that bismuth medication protects rabbits from infection for a month or more. The prophylactic efficiency of iodo-bismuthate is claimed to be about twice the curative action. Apparently the best way of utilising this property of bismuth is to have some preparations which can be taken by the mouth before exposure, *e.g.*, glycerite of bismuth.

Brigham treated a number of patients suffering from syphilis with glycerite of bismuth, administered orally, with marked clinical and serological improvement. The dose administered is usually 20 minims (1.3 c.cm.) three times a day. In weak and debilitated patients this may produce slightly toxic effects, *e.g.*, soreness of the gums when the dose is reduced, these symptoms quickly disappear. Glycerite of bismuth has long been used as a tonic, and patients usually remark that they feel much better after taking this preparation*. This form of bismuth should be administered for a period of three months, and after a brief rest for another 3 months in old standing cases. The advantage over injections is that the patient gets a continuous daily supply of bismuth, and not in large doses at frequent intervals.

Yaws or Framboesia. Yaws is a chronic disease of warm-climates caused by the *Spironema pertenu*. As regards causation and the general course of the disease, it closely resembles syphilis. As a result of its successful use in syphilis, bismuth has naturally been employed in the treatment of yaws. Extensive trials in British East Africa have shown that bismuth

compounds are nearly as efficacious as neo-salvarsan. Two or three injections of tartro-bismuthates in doses of 0.2 gm. in freshly prepared solutions at intervals of a week produce healing of the lesions, but it is probable that a larger number will be required to eradicate the parasites. Besides bismuthyl tartrates, bismuth subgallate (dermatol) has been used in 3 c.cm. doses of a 10 per cent. emulsion in oil given intramuscularly twice a week. Very good results were obtained with 10 injections, but this produced toxic effects. On a large scale patients have been treated with a single massive dose of dermatol; only 15 per cent. relapsed. Good results have been claimed with four weekly injections of bismuth subnitrate in 10 per cent. suspension in oil. Metallic bismuth has been used but this is more expensive. Bismutho-yatren A and Bismutho-yatren B have given good results; 2 to 17 injections on an average have to be given. The author has tried *bismene* in doses of 0.1 to 0.15 gm. intravenously in a few cases with good results. The results are as good as those with neo-salvarsan and other bismuth preparations; it is much cheaper, more stable and costs less than a farthing a dose. Shircore (1926) treated 113,000 cases of yaws in secondary and tertiary stages with 6 injections of bismuth arsanilate given every other day; 75 per cent. were completely healed. Although bismuth preparations are admirably suited for mass treatment of this disease, recent work has shown that to eradicate the disease, a combined treatment should be carried out with bismuth and arsenicals till the serum reaction becomes negative.

Amoebic dysentery. Deeks (1908) first started treatment of dysentery with large doses of bismuth subnitrate by the mouth in Panama and found that it gave very promising results. In seven cases 180 gr. of the drug were given in effervescent form every three hours night and day; in chronic cases the dose is less but it is advisable to continue one or two daily doses for at least a month after convalescence is established. After the introduction of emetine, the treatment with bismuth subnitrate was supplemented by daily injections of emetine. James (1913) studied the effects of both bismuth and emetine on the vegetative forms of *E. histolytica* and found that the amoebæ passed by patients on emetine and bismuth treatments showed signs of degeneration but the changes produced differed with the two drugs. He suggested that bismuth subnitrate may be converted into bismuth sulphide in the gut and that in

this way it may deprive the amoebæ of hydrogen sulphide, which is possibly an essential element of their food supply. He advocated a course of 9 to 12 gr. of emetine by injections and 3 dr. of bismuth subnitrate suspended in water, by the mouth every 3 or 4 hours. Deeks (1914) thought that with the combined emetine and bismuth treatment every case of amoebic dysentery might be cured. James (1916) concluded that intestinal amoebiasis whether acute or chronic can be eradicated with liquid diet until the stools are formed, along with emetine injections carried to the point of physiological reaction and bismuth in not less than a teaspoonful dose 4 times a day carried over for a period of several weeks. York (1919) spoke very highly of the combined bismuth and emetine treatment and said that the treatment invariably cleared the stool of entamoebæ, a result which can by no means be achieved by emetine alone. James and Deeks (1924) gave an account of cases of amoebic dysentery treated with bismuth subnitrate alone in Panama, none of which relapsed. They believe that certain products of putrefaction are essential for the life of amoebæ, and that bismuth acts either by destroying the putrefactive bacteria, or by neutralising some products essential for the life of the amoebæ. Deuskar (1926) tried this treatment with excellent results in the Andamans. Knowles (1928) in a series of 55 cases found that the combined method failed to eradicate the infection from carriers, the proportion of probable cures to failures being 1:1.8 in his cases. He found that the treatment certainly improves results from the clinical point of view. James (1928) believes that the prolonged use of bismuth subnitrate in large doses, 12 to 14 gm. per dose, 3 to 5 times a day, combined with rest, irrigation of the gut when indicated and a proper diet, will give a high percentage of cures. He gives emetine according to the susceptibility of the patient to the drug. The patient is given a rigid, but nutritious diet and has to take bismuth for several months.

It will be seen from the above that combined treatment with emetine and bismuth is worthy of further trial. It is advisable to use bismuth carbonate instead of the subnitrate as the latter sometimes gives rise to nitrite poisoning due to absorption of the drug from the ulcerated areas.

Lupus erythematosus. This is a chronic non-tuberculous affection of the skin characterised by disc-like patches on the surface with reddish edges and depression at the centre. The patch is covered with scabs which fall off gradually and leave a dull white cicatrix at the bottom. The etiology of the disease is unknown. Bismuth salts have been used in this condition with good results. Bismuth metal, bismuth hydroxide, bismuth oxychloride, or sodium bismuth thioglycollate suspended in oil is given intramuscularly once a week. The average dose ranges from 0.3 to 0.4 gm. Local treatment with mercury improves the condition in many cases.

MODES OF ADMINISTRATION

By the mouth. As already stated, only very minute quantities of bismuth are absorbed from the alimentary canal. The absorption is so slow and uncertain that this route of administration is not employed for the treatment of such diseases as syphilis. Tartro-bismuthates have been given orally but they are slowly absorbed and their effects are uncertain.

Subcutaneous and intramuscular injections. Subcutaneous injections of the soluble salts usually produce severe local reactions and, as they have no advantage over the intramuscular route, this route cannot be recommended.

Intramuscular injections of bismuth salts are said to be as effective therapeutically as intravenous injections. Bismuth therapy involves the same principle as intramuscular mercury therapy, *i.e.*, to establish intramuscular depots of slowly-soluble metal compounds, which may be gradually but continuously absorbed. The same difficulties are met with here, namely, that the absorption of the drug from these depots becomes progressively weaker till finally arrested by local fibrosis. The patient thus has a number of bismuth nodules in the body which do no good, but may do great harm if several of them suddenly break up or become otherwise activated.

'Trepol' and 'neo-trepol' are given intramuscularly with a thick needle in the superior gluteal region. Injections are given alternately on either side, not oftener than once a week as there is danger of cumulative poisoning. The injections are repeated until the Wassermann reaction becomes negative. Some authorities give 0.1 gm. at intervals of a fortnight. If symptoms of flatulence occur, especially in the morning, the interval between the doses should be increased.

Local reactions due to muscle irritation and necrosis may follow intramuscular injections. Pain and inflammation vary according to the nature of the compound used and the vehicle employed. The common type is a hard and painful swelling with considerable infiltration which may sometimes suppurate. The addition of 10 minims of a 2 per cent. butyn solution or phenol (1/5 gr.) to trepol reduces the pain effectively though

an area of tenderness may be left. Histological examinations five days after injection show varying degrees of necrosis of muscle cells and leucocytic infiltration. Watery solutions produce a more intense reaction than the oily solutions. Nodules in the tissues left after intramuscular injections of bismuth compounds are due to purely inflammatory reactions and are less likely to be produced when solutions are made in vegetable oils such as olive or almond oil.

Intravenous injection. The intravenous injections of soluble bismuth salts are so toxic that they cannot be recommended. The toxicity by this route is at least ten times greater than the intramuscular route.

As in the case of other heavy metals, agglutination and hæmolysis may occur after intravenous injections, with the formation of emboli. Even with such compounds as tartro-bismuthates, colloidal preparations or bismuth hydroxide, reactions may be produced immediately after injections. Cases of sudden death after intravenous injection of bismuth compounds with symptoms of colloidal shock have been reported. Kolmer (1926) is of opinion that the dangers of intravenous injection of tartro-bismuthates have been overrated, but he says that the intravenous route is not the method of choice, as absorption after intramuscular injection is fairly rapid. In acute cases of syphilis, when arsenicals cannot be given owing to hypersensitiveness, the intravenous route is preferable. Kolmer gives 0.01 gm. (1/6 gr.) of potassium tartro-bismuthate dissolved in 10 c.cm. of saline solution and sterilised by heating; no untoward effects are produced. Mercury is more toxic by the intravenous route than bismuth, the maximum tolerated dose of perchloride of mercury is 0.006 gm. per kilo., while that of the soluble tartro-bismuthates is 0.02 to 0.03 gm. Some authorities have shown that the danger of agglutination of erythrocytes is small, but bismuth may produce precipitation of serum-proteins in the same way as do the arsenicals or antimonials.

CHAPTER XXXIII

TOXIC EFFECTS OF BISMUTH

The toxicity of bismuth compounds has been worked out on animals. The earliest symptoms following intravenous injections of bismuth salts in experimental animals are loss of appetite, nausea, vomiting and diarrhoea; salivation and stomatitis with ulceration of the gums, tongue and buccal mucous membrane appear shortly afterwards. Weakness, slowness and inco-ordination of movements follow and tetanic convulsions may occur at intervals. The urine contains albumin and casts. The weakness gradually deepens into complete paralysis and the animals generally die. Post-mortem examination shows congestion and sometimes necrosis of the kidneys. Congestion and a black discolouration of the cæcum and upper part of the large intestine are also prominent features. The mucous membrane may show areas of patchy hæmorrhage, ulceration or necrosis. The histological changes produced in the kidneys and liver of rabbits, suffering from bismuth poisoning, following the administration of tartro-bismuthates, have been studied. These changes chiefly affect the convoluted tubules, the epithelium of which shows all kinds of degeneration ranging from severe cloudy swelling to extreme necrosis and calcification; the glomeruli are not affected. The lesions in the liver are not so marked; usually cloudy swelling of the cells, and fatty degeneration are met with; hæmorrhagic and necrotic foci may rarely occur. Following intramuscular injections in guinea-pigs, the changes produced in the liver and the kidneys are of a much milder nature than those produced by intravenous injections. Such experiments show, (1) that intramuscular injections are less toxic than intravenous injections and (2) that bismuth is most toxic for the kidneys, next for the liver and relatively non-toxic for the brain, heart, lungs, suprarenals and spleen.

Changes in human beings appear to be of the same nature, and symptoms are similar to those produced in animals. The toxicity of bismuth is comparatively low, undesirable effects are

comparatively few and generally not serious. In view of the extended use of bismuth in syphilis, these will be given in detail.

Symptoms. After intramuscular injection of tartro-bismuthates, the earliest symptoms observed are pain in the muscles and joints accompanied by loss of appetite and feelings of malaise and lassitude. These, as a rule, are not severe, but in exceptional cases intense pain in the larger bones, joints and groups of muscles, accompanied by rigors, fever, a feeling of compression in the chest and dyspnoea may occur a few hours (12 to 24 hours) after the injection. Rheumatoid pains of the ribs, spine and legs are characteristic; skin eruptions of the nature of erythrodermia or scarlatiniform erythema with purpura may occur. Jaundice is as a rule not met with and bismuth may be given to patients in whom arsenicals have produced jaundice. Local irritation at the site of intramuscular injection is not uncommon; a 'lead-line' may occur at the junction of the teeth and gums due to precipitation of bismuth sulphides; a blue line in the gums, odorous breath and bad taste in the mouth often precede it. Blue spots may appear under the tongue and in the mucous membrane of the cheeks; gingivitis is caused by the deposition of bismuth in the capillaries, producing partial blockage of vessels, congestion and loss of nutrition and formation of ulcers. Ptyalism is unusual and when present is not so severe as in the case of mercury. Bismuth is less likely to produce renal irritation than mercury, and albuminuria is therefore very uncommon even after 12 to 15 intramuscular injections of 0.1 to 0.2 gm. each of tartro-bismuthates. It is however advisable to examine the urine every week during the course of injections. Herxheimer's reaction, *i.e.*, pain and swelling of syphilitic lesions in the lymph glands, skin, etc., are sometimes seen after 2 or 3 intramuscular injections; vague pain in the heart and other parts of the body, which are probably due to provocative effects, sometimes occur. These effects however are not so common as with the arsenicals.

Toxic symptoms produced in human beings by the oral administration of bismuth subnitrate may be due, not to bismuth but to the nitrate portion which is reduced in the gut to nitrite and produces symptoms of nitrite poisoning. After a

large dose of this compound for radiography, methæmoglobinæmia, intense cyanosis, diarrhoea, dyspnoea and collapse may occur; death may even occur from paralysis of respiration. All these can be prevented by using bismuth subcarbonate instead. Considerable absorption of bismuth may however take place from wounds and raw surfaces and symptoms of acute or chronic poisoning may follow. Capillary thrombosis from precipitation of bismuth sulphide in the intestinal vessels has been known to occur.

Intramuscular injections and injections of bismuth compounds into long sinuses sometimes give rise to toxic phenomena, from excessive absorption of the metal. The condition of the patient is an important contributing factor. If the mouth and the gums are in bad condition there may be gingivitis, stomatitis, and halitosis (offensive breath); if the patient is a victim of gastro-intestinal disorders, he is more likely to suffer from diarrhoea and colic; focal infection of the teeth, tonsils and other tissues may predispose to dermatitis. Some individuals are naturally hypersensitive to bismuth. According to Kolmer, four factors are concerned in the production of toxic symptoms, (1) the drug, (2) the route of administration, (3) predisposing pathological state of individual patient and (4) hypersensitivity to bismuth.

The circulatory depression, that is noticed in animals receiving intravenous bismuth, does not occur after the clinical use of bismuth as an anti-syphilitic. Sometimes acute reactions due to colloidal shock may occur. The symptoms complained of are dizziness, pallor, rapid and weak pulse, dyspnoea, convulsions and collapse. Siderosis, halitosis, ptyalism, and gingivitis are commonly observed; various skin eruptions (purpuric, scarlatiniform, erythematous, urticarial, lichenoid, exfoliative dermatitis), renal irritation and provocative Herxheimer's reactions are sometimes seen. Stomatitis and gingivitis are the most troublesome symptoms.

The mechanism of production of siderosis, stomatitis, and allied lesions has been explained, but the muscle and bone pains are more difficult to interpret. These are probably due to a neuritis similar to that produced by arsenic and mercury.

Treatment of toxic reactions. In poisoning from large doses of bismuth compounds by the mouth, the stomach is washed out thoroughly and repeatedly and saline purgatives are administered. If bismuth paste has been given in a sinus it should be removed.

In case of acute poisoning due to a large accidental dose, the most dangerous lesion is tubular nephritis. If this is produced intravenous injections of sodium thiosulphate are indicated. As a rule muscular pains, malaise and anorexia disappear after a few injections, but if they persist and there is anæmia, loss of weight or ulceration of the gums, the treatment should be stopped. For gingivitis and stomatitis a mouth wash containing alum and potassium chlorate is the best. Ulceration of the gut is relieved by proper dietary and demulcents.

Cautions and contraindications. Before beginning a course of bismuth a thorough investigation must be made into the condition of the teeth, the liver function and the general health of the patient. If there is any such defect, refrain from giving the treatment till these have been attended to. Cleansing of the teeth and gums during the course is important; dietetic errors should be corrected to reduce the possibility of gastro-intestinal disturbances, such as diarrhoea and colic; the appearance of large quantities of albumin and casts in the urine also calls for suspension of treatment; if albumin had been present prior to treatment, soluble salts are better. The urine should always be examined before starting bismuth injections and during the course. In exceptional cases renal function tests may be necessary but liver function tests are not required. Sometimes a general asthenia with pallor and loss of weight occurs after bismuth injections, but this soon passes off. The drug has not yet been used long enough to warrant any definite opinion. We are only just beginning to find these out in the case of arsenicals and mercury compounds.

Modes of action of bismuth compounds. The mechanism by which bismuth compounds produce their spirochaeticidal action *in vitro* and *in vivo* is not clear. Tartro-bismuthates of sodium and potassium are capable of destroying the motility of *S. pallida* in very high dilutions,

and bring about their complete destruction when given by inoculations in rabbits. In both these respects mercuric chloride and mercuriochrome are more active than bismuth compounds. Levaditi believes that bismuth enters into a colloidal state and exerts a direct spirochaeticidal effect in this condition. The mechanism is probably similar to that of mercury and is largely dependent on the ease with which the bismuth ions are dissociated. There is no evidence to show that new compounds are formed by processes of oxidation or reduction, as is the case with organic arsenicals or antimonyl compounds. There is also no evidence to show that bismuth increases the production of spirochaeticidal antibodies by direct stimulation of the antibody-producing tissues. Kolmer (1926) stated that the concentration of bismuth attained in the blood after intramuscular injections is cumulative and is probably sufficient to kill spirochaetes. It is possible that the actual destruction of the parasites is due to the union of the metal with the proteins of the parasites.

It has been said that bismuth is activated by the body tissues into a hypothetical bismo-protein called *bismoxyl*. The power of tissues to transform bismuth into bismoxyl depends upon their glutathione content. It has been shown in the experimental syphilis of rabbits that bismoxyl cures syphilis not merely by stimulating the tissues and general immunity reactions, but by an actual destruction of treponemas. The therapeutic action of bismuth varies directly with the quantity of bismoxyl circulating in the body; this is termed the tissue-metallic potential. It would appear that the potential is higher when insoluble salts are used rather than metallic bismuth. Intravenous injections of bismuth compounds therefore seem to be inadvisable if this is correct.

Levaditi and Howard (1929) showed that when an extract of liver or suprarenal in saline is incubated at 37°C. with bismuthyl tartrates of sodium and potassium for three hours, and then flocculated at 70°C. for three hours, a precipitate is obtained. This precipitate, suspended in normal saline and injected intramuscularly in rabbits, cured them of syphilis in doses of 0.00125 gm. of metallic bismuth per kilo. body weight and even doses of 0.000312 gm. cured after some time. They suggested that minute quantities of metallo-proteins act synergetically with the immune bodies of the tissues.

PREPARATIONS OF BISMUTH

During the last five years a large number of new compounds, chiefly organic have been introduced for intramuscular and also for intravenous injections. Many of these are still in the experimental stage. While as a general rule those having the highest percentage of the element are the most effective, it must be borne in mind that the form in which bismuth exists and the manner in which it is

combined have much to do with the efficacy of the product. The ease and rapidity with which bismuth ions are dissociated in the body, as has been already pointed out, are important factors in their therapeutic action. In order to form a clear conception of the nature of action of these compounds, it will be advantageous to consider the physical and chemical properties of bismuth. Bismuth is situated close to arsenic and antimony in the periodic system of elements. Like arsenic and antimony, bismuth is an amphoteric element and therefore yields cation (electropositive bismuth) and anion (electronegative bismuth) compounds. The majority of bismuth compounds in current use are electropositive or cationic. The bismuth content of these products varies from about 20 to 80 per cent. These preparations can be grouped into four general classes:—(1) insoluble, suspended in aqueous medium, such as the metal in dextrose solution; (2) insoluble, suspended in oil, such as bismuth salicylate in oil; (3) soluble, suspended in oil, such as potassium bismuth tartrate; (4) soluble, dissolved in aqueous medium, such as bismuth sodium tartrate in sucrose solution or water.

The products containing electronegative or anionic bismuth have come into use more recently. They are represented by two general types:—(1) soluble haloid bismuthites with about 21 per cent. of bismuth, *e.g.*, sodium iodo-bismuthite in ethylene glycol; and (2) sodium bismuthate with about 73 per cent. of bismuth. Electronegative bismuth compounds are claimed to possess several advantages over the electropositive compounds though both series of compounds are in common use. Electronegative bismuth penetrates the cerebral tissues better and therefore is to be preferred in neurosyphilis. These compounds are better absorbed and have a much lower toxicity than the cationic products. Most of the compounds at present known are toxic, but further research will probably give us compounds which are more parasitotropic and less organotropic.

A number of preparations of bismuth have been introduced recently for the treatment of syphilis. Those generally used are:—

I. Preparations containing metallic bismuth.

Metallic bismuth 0.2 gm. in 1 c.cm. of 5 per cent. glucose solution is sold in ampoules for intramuscular injections. Dose 0.5 to 1 c.cm. **Bismotab** is a preparation of 20 per cent. bismuth in 5 per cent. glucose solution; dose 0.5 to 1.0 c.cm. **Neo-trepol** is a 10 per cent. suspension in sterile isotonic saline solution. Dose 1.5 to 2.0 c.cm. intramuscularly every week. **Bismuthyl** is a 10 per cent. suspension in glucose medium. Dose 2 c.cm. every 5 days until 12 to 15 doses.

Metallic bismuth preparations are preferred to others on account of their being non-toxic; their absorption rate is uniform and the action is steady. They are specially useful in syphilitic affections of the heart and the nervous system. Care should be taken during intramuscular injection that none of the drug gets into the blood stream, as

this may cause paralysis and death in two hours. Metallic bismuth can also be given by deep subcutaneous injections.

Colloidal bismuth has been given intramuscularly as well as intravenously. Experiments on rabbits, guinea-pigs and dogs show that it can be given in high concentrations. The toxic dose for the guinea-pig is 0.095 to 0.35 gm. per kilo.; concentrations up to 4 per cent. do not produce shock, embolism or death. Signs of toxic action are tremors, convulsions, congestion and hæmorrhage in the kidneys, liver and intestines.

II. Inorganic preparations of bismuth.

Bismuth hydroxide suspended in, (1) water and glycerine, (2) in sterile oil, containing minute traces of mesothorium bromide.

Muthanol is a suspension of the radio-active oxide in oil; it is sold in ampoules of 2 c.cm. containing 0.15 gm. of bismuth oxide.

Casbis is a sterile oily suspension of activated hydrate of bismuth. In consequence of the very fine state of subdivision, it is remarkably free from causing any irritation when injected. It is slowly absorbed and produces a continuous and well-sustained effect. The dosage, to begin with, is 0.5 c.cm., followed by 1 c.cm. at an interval of 3 days—a total of about 15 to 20 c.cm. being necessary. Children should have a starting dose of 0.05 c.cm., followed by 0.1 to 0.2 c.cm., to a total of 1.5 to 2 c.cm.

Bismol is an oily suspension of bismuth containing 0.15 gm. of bismuth hydroxide in 2 c.cm. of oil. It is said to be satisfactory in florid types of syphilis. **Sodium bismuth iodide** (sodium iodo-bismuthite) in ethylene glycol containing 0.1 per cent. acetic acid, each c.cm. containing the equivalent of 0.012 gm. bismuth. This preparation has been introduced by Hanzlik and his co-workers. It is well-tolerated locally and internally and is fairly rapidly absorbed and excreted; and as it appears in the cerebrospinal fluid, it seems worthy of trial as a preventive of neurosyphilis or for its early treatment.

Bismuth oxychloride. Lomholt recommends the use of a watery preparation (suspension) of bismuth oxychloride (bisoxyl), so prepared that the particles have a diameter of from 3μ to 4μ . He considers that this preparation is sufficiently non-irritant and gives a correct rate of absorption of the metal.

III. Organic preparations.

Alkaline bismuthyl tartrates. These compounds can be divided into two classes.

(1) *Neutral* compounds known as *Bismuthyl tartrates* or *Carbo-bismuthates* which are either soluble or insoluble. They are prepared by dissolving bismuth oxy-tartrate in alkali, the alkali bismuthyl tartrate being obtained as a powder by evaporation or precipitation with alcohol. They are used for injection against protozoal disease. The

neutral compounds for injection are sodium tartro-bismuthate, potassium tartro-bismuthate and sodium potassium tartro-bismuthate.

(ii) *Acid preparations*, frequently described as "bismuth tartrate soluble." They are obtained by treating bismuth hydroxide with a solution of the alkali acid tartrate.

A number of proprietary preparations similar in composition has been put on the market under various trade names; **Trepol** is tartro-bismuthate of sodium and potassium. Dose 3 gr. (0.2 gm.) intramuscularly every week till 2 to 3 gm. are given. This compound is also given in 10 per cent. suspension in sterile oil. Ampoules or sterules containing 3 gr. (0.2 gm.) in 30 minims (2 c.cm.) of water are sold under the name of **Bismutol**. **Luatol** is a tartrated bismuth preparation; dose 1 c.cm. of the aqueous solution containing 0.1 gm. of the compound. A course consists of 10 to 20 c.cm. given in weekly injections of 1 to 2 c.cm. **Bismoluol** is a dipotassium bismuth preparation. A suspension of potassium bismuthyl tartrate in a medium containing sulphur has been used.

Bismuth salicylate is a white powder insoluble in water, alcohol and glycerine which has been used for intramuscular injections. **Bisantol** has been introduced by May & Baker, Ltd. It is a 10 per cent. solution of bismuth salicylate in neutral vegetable oil, 1 c.cm. of the suspension containing 0.057 gm. of metallic bismuth. The injections are said to be painless. The course of treatment comprises 12 to 15 injections of 1 c.cm. of the suspension, given intramuscularly at intervals of 3 to 5 days. **Sodium bismuth thioglycollate** is a water-soluble preparation. **Thiobismol** is a similar preparation containing 37.5 per cent. of metallic bismuth. It is said to be non-irritating and to influence the disappearance of the spirochaetes more favourably than insoluble bismuth preparations. The dose for each injection is 0.2 gm. of the powder, given intramuscularly dissolved in 1 c.cm. of distilled water. **Bismuthyl gluconic acid** and the sodium salt of bismuthyl saccharic acid have been used in 10 per cent. watery solutions. **Bismuth camphor carboxylate** (**Bismocymol**) is a white powder with a camphoraceous odour. A suspension in oil is used, 1.0 c.cm. containing 0.05 gm. of bismuth. Kolmer states that it produces less local reaction than insoluble bismuth compounds and that it has proved of great value in the treatment of children and also adults who do not usually tolerate intramuscular injections. Constitutional reactions and signs of renal irritation have not been observed. **Bismogenol** is a compound of bismuth and hydroxybenzoic acid and **Mitamel** which is said to be a compound of bismuth and trichlorobutylmalonic acid are German preparations.

Chopra and his collaborators have introduced an organic aromatic compound of bismuth known as **Bisenene**. This compound is practically the bismuth analogue of urea-stibamine and therefore is the sodium salt of para-amino-phenyl-bismic acid in combination with urea. It

contains 50.1 per cent. of bismuth and has a low toxicity, its M.L.D. being 500 mgm. per kilo. in white mice. This compound can be given intravenously without producing toxic symptoms. Its value in syphilis has not been determined but is quite effective in the treatment of yaws. It is possible that this series of aromatic compounds may have some potent therapeutic properties.

IV. Alkaloidal iodo-bismuthates. A number of these compounds were prepared of which iodobismuthate of quinine or **Quinby** is commonly used. **Biquinyl** is a commercial preparation of iodo-bismuthate of quinine and bismuth oxychloride.

V. Liposoluble bismuth compounds. Various bismuth compounds soluble in lipids have been prepared, instead of suspensions of bismuth. **Emblal** (540 D Merck), **Blazan** (methyl-hydrocinnamate) are such compounds; **Spirobismol** is a double iodide of quinine and bismuth associated with lecithin. It is said to be specially suitable for syphilis during pregnancy. **Bismuth camphor carboxylate** (Cardyl) and basic Bismuth α -carboxylethyl- β -methyl-nonoate (**Bivatol**) have been studied. The chemotherapeutic index of the latter compound is 1:33 for rabbit syphilis, and it is rapidly absorbed. Not only do the primary lesions rapidly heal, but the infection is totally eradicated as the animal becomes susceptible to infection with *S. pallida* again. The action of **Bivatol** has been favourably reported on by several workers both in England and in Europe. It is available as a neutral limpid oily solution containing 40 mgm. of bismuth metal per c.cm. The dose is 2 c.cm. of the suspension given intramuscularly twice a week—a course comprising 12 injections. Levaditi regards it as the treatment of choice in syphilis. The fact that it is a solution and not a suspension ensures exact dosage, while the slow rate of absorption avoids shock and toxic disturbances. Schwartz speaks very highly of this liposoluble compound, which he has used in all stages of syphilis with most favourable results. **Biloposol** is similar in composition to bivatol. It contains 0.04 gm. of bismuth per c.cm. of the suspension and is given in doses of 2 c.cm. twice weekly. Its rate of excretion is very slow and may continue for as long as one and a half to two months after cessation of treatment.

VI. Compounds of bismuth and organic arsenicals. It is generally recognised that combined treatment with bismuth and arsenic is more effective than either drug alone. Efforts have therefore been made to present a compound of bismuth and arsenic in such a form as to get the therapeutic effects of both drugs simultaneously. **Bismarsen** or bismuth arspenamine sulphionate is the sodium salt of a bismuth derivative of arsenobenzene methylene sulphonic acid with inorganic salts. This is an American product and contains approximately 15 per cent. of arsenic and 23.25 per cent. of bismuth. It is given intramuscularly twice weekly, in doses of 0.2 gm. dissolved in

1 c.cm. of distilled water to which 2 min. of 2 per cent. butyn is added, the full course being 24 to 32 injections. Its spirochaetocidal effect is considered by some to be slower than that of the arsenical compounds and its healing effects not so marked. In early syphilis this compound was very effective, toxic effects were few, and there was a definite tonic effect. In neurosyphilis it has no effect, though it is said to relieve the lightning pains of tabes; it had no effect on optic atrophy. The drug is well borne by children. Levaditi (1926) described bismuth stovarsol or **Bistovol** which is basic acetyl-amino-oxyphenyl-arsenate of bismuth which did not prove very effective against syphilis. He has also prepared soluble **Bistovol** (H13) which is p-hydroxy-m-acetyl-amino-phenyl arsenic acid, bismuth salt of p-amino-phenyl arsenic acid and bismuth tryparsamide-n-phenyl glycinamide-4-arsenic acid. The first has a well-marked antisyphilitic action, having a therapeutic index of 1.35 in syphilis in rabbits. It can be given in 2 per cent. solution intramuscularly, is quite painless and produces rapid healing of primary and secondary lesions. It can be given by the mouth in solid form or as 10 per cent solution and was tolerated in 2.0 gm. doses daily for 8 to 11 days. Even with this high dosage no toxic symptoms were produced and lesions healed; serological reactions improved. **Bismuth arsanilate** is given as a suspension in oil intramuscularly and has a therapeutic efficiency equal to that of bistovol. Bismuth tryparsamide contains 40.5 per cent. bismuth and 14.5 per cent. arsenic. This preparation was tested by Levaditi (1928) in natural spirochaetosis of the rabbit (*S. cuniculi*). The spirochaetes disappeared on the second day after intramuscular injection of 0.1 gm. per kilo. Its curative action is somewhat slower than that of bistovol or bismuth arsanilate.

Bismuth-yatren is said to be an aqueous solution of sodium bismuth-iodohydroxy quinoline sulphonate, containing 10 mgm. of metallic bismuth per c.cm. **Bismuth-yatren B** is a quinine derivative and contains 36 mgm. of metal per c.cm.

Mesural contains mercury and $1\frac{1}{2}$ gr. (0.11 gm.) of bismuth in each c.cm. It is given by deep intramuscular injections, 0.5 c.cm. being the first dose in an adult, increased to 1.0 c.cm. Eight to twelve injections giving a total of 14 to 20 gr. (1.0 to 1.3 gm.) constitute a course.

Quinine-iodo-Bismuthate occurs in the French Codex Supp. 1929; dose 0.15 gm. usually given suspended in olive oil. **Bi-quinyl** is a double iodide of quinine and bismuth; ampoules containing 0.3 gm. in 3 c.cm. of oil are on the market. These preparations were introduced with the idea that the combination of quinine and iodine with bismuth will enhance the spirochaetocidal action.

*Bismuth Preparations for Injection in Syphilis**(Modified from Harrison)*

Chemical compound	Medium	Trade names	Content of bismuth in per cent. of the dried compound
*Bismuth metal	Isotonic saline Creo-camphor base.	Neo-trepol Bicreol	96

CHAPTER XXXIV

MERCURY AND ITS DERIVATIVES

Mercury was the first drug to be used as a specific disinfectant for the body tissues, for it was employed in Europe in the treatment of syphilis as early as 1500 A.D., and until the discovery of arsphenamine in 1905 it remained the only effective remedy against this disease. Its importance as a therapeutic agent in syphilis has suffered a set-back of late years as it has been replaced by bismuth. Mercurials have however a powerful destructive action on some of the pathogenic protozoa and a number of new mercury compounds have been introduced in medicine during recent years. Renewed interest has therefore been created in the subject, and it has been thought necessary to discuss these in some detail.

PHARMACOLOGICAL ACTION

External action. Mercury has a powerful toxic action on all protoplasm and mercurial compounds for this reason are active germicides. This germicidal effect depends chiefly on the concentration of mercuric ions in their solution, and on the precipitation of proteins. Absence of protein precipitation is important because it diminishes local irritation, favours the penetration of the mercury and obviates the absorption of the mercury ions by the precipitates.

A large number of mercury compounds are used externally for their antiseptic and germicidal properties. Sollmann has classified them according to the degree of their ionization, as this seems to be the most important factor which governs their bactericidal action.

Class I. Simple highly-ionizable inorganic mercuric salts. Mercuric chloride is one of the important members of this group. It is a most powerful antiseptic and inhibits the growth of many micro-organisms in as low a dilution as 1 in 300,000. Non-spore-bearing bacteria are killed in dilutions of 1 in 20,000 but anthrax bacilli are killed only in 1 in 1,000 concentration. Tubercle bacilli are rather resistant. *In vitro*, *Treponema pallida* are killed in dilutions of 1 in 200,000. Mercury has a stronger affinity for spirochaetes and the related group of organisms, but it has little effect on the parasites of malaria and sleeping sickness. Its practical utility however is limited, on account of its poor penetration due to the precipitation of proteins and its toxicity. It is used as

an antiseptic lotion for sterilising the hands, in a strength of 1 in 1,000. As the solutions are irritant to mucous membranes and have a corrosive action, they should be used with caution. One in 20,000 to 1 in 10,000 is quite effective and if stronger concentrations are used, inflammation of the mucous membrane and serous surfaces may be produced. The coagulation of the proteins gives a peculiar ashy corroded appearance to the mucous membrane. The tissues underneath present a reddened appearance and prolonged contact may lead to necrosis.

Class II. Moderately ionizable mercuric compounds. Potassium mercuric iodide is a typical example. This compound is obtained by dissolving mercuric iodide in a slight excess of potassium iodide. The antiseptic activity of this compound is practically the same as that of mercuric chloride, but the local irritant effect is much less. It tends also to get precipitated in contact with the tissues on account of the rapid diffusion of the alkaline iodide.

Class III. Poorly ionizable mercuric compounds. Mercuric oxycyanide, cyanide and benzoate, produce very little irritation of the mucous membranes and unlike other salts can be used for their antiseptic effect on sensitive surfaces such as the conjunctiva, and urethra. Several organic compounds belonging to this class have been prepared, *e.g.*, novasurol, meroxyl, mercurosol, afridol, metaphen. These have largely displaced the oxycyanide and cyanide compounds. Meroxyl may be used in concentrations ranging from 1 in 1,000 to 1 in 200 and merbaphen in concentrations of 1 in 10,000 to 1 in 1,000. Novasurol and salyrgan are not used as external antiseptics.

Class IV. Mercuric fluoresceins. These compounds were first introduced in 1919 and are characterised by their non-irritant properties when applied to the skin and mucous membranes. Mercurochrome 220 soluble is the most important member of this group. Flumerin (sodium hydroxy-mercuri-fluorescein) is also sometimes used, though it is recommended intravenously for syphilis.

Mercurochrome is now considered to be a highly efficient non-irritant antiseptic and is being widely used. A 2 per cent. solution causes only slight and brief irritation of sensitive mucous membranes, *e.g.*, the urethra. It is used especially in genito-urinary practice but has not received much popularity as an antiseptic for the skin and the mucous membrane of the mouth, throat, etc., as it cannot penetrate the tissues to any great extent and only acts on the surface bacteria and is ineffective against the spore-bearing organisms. It will be dealt with at length later.

Class V. Water-insoluble mercurials. These do not produce any immediate effects, but since they are gradually dissolved by the proteins and salts of the tissues they develop some local irritation and antiseptic action. Yellow mercuric oxide and ammoniated mercury are commonly used in ophthalmology and dermatological practice. Calomel

has also been used as a dusting powder for sluggish ulcers, ulceration of the cornea, etc. A 33 per cent. ointment is employed as a prophylactic against syphilis. A mild mercurial ointment which contains 30 per cent. of finely divided metallic mercury is used for destruction of lice.

Nature of the bactericidal action of mercury. The nature of the bactericidal action of the different mercury compounds is difficult to explain. The differences in the degree of solubility and ionization of the various salts and compounds are no doubt very important factors as has been rightly stressed by Sollmann. There are however certain factors which cannot be satisfactorily explained. Thus for example, salts like mercuric nitrate and mercuric acetate are much less powerful antiseptics and have a much less disinfectant action than mercuric chloride, though the above salts are equally freely dissociable. The peculiarities in the action of mercury externally are probably due to its action being dependent upon absorption. This causes mercury to act upon bacteria in high dilutions, but a certain time is necessary for absorption to occur, and any other substance that absorbs mercury will prevent it from acting upon the bacteria. The mere absorption of mercury upon bacteria does not kill them, but sufficient time has to be allowed for the mercury to penetrate into the organism before death occurs.

Internal Action. The internal action of mercury compounds, specially those in organic combination, will depend upon their solubility and diffusibility. The organic compounds are probably broken down into simpler substances in the tissues, the dissociation occurring in successive stages, and the intermediate compounds, whatever their structure may be, will possess probably the same pharmacological action as that exhibited by the original compound.

Respiration. The respiration is accelerated and deepened with moderate doses of mercury, probably due to stimulation of the medulla; large doses paralyse respiration; 2 to 4 mgm. of mercury per kilo. brings about these changes in respiration and circulation in the animals and 6 mgm. per kilo. may be regarded as the average dose necessary to cause paralysis of respiration.

Circulation. Blood pressure. Intravenous injections of soluble inorganic salts of mercury in animals such as dogs, cats and rabbits produce an abrupt, marked and persistent fall of blood pressure, there may be an initial rise of pressure in some cases. The changes in the blood pressure produced by injection of the organic mercury compounds are milder. Jackson (1926) using organic mercury compounds found that about 3 c.cm. of a 2 per cent. solution caused an elevation of pressure instead of a fall, the rise being most marked with 'salyrgan'. Subsequent injections produce smaller rises of pressure till a fall replaces the rise produced by the early injections.

Heart. The action of small amounts of mercury upon the heart was first studied by Dreser (1893) who found that as little as 3.8 mgm. of mercury potassium thiocyanate in 40 to 50 c.cm. of defibrinated ox blood resulted in paralysis of the perfused frog's heart, but that equal or larger quantities of mercury hyposulphate had no effect. The inorganic salts and so also the organic compounds, such as mercurochrome, rapidly produce cardiac irregularities and fibrillation.

The response of the isolated heart to the action of mercury varies in different animals. The frog's heart is very resistant to the action of mercury and a concentration as high as 1 in 50,000 is necessary to show any marked effect. The turtle's heart responds in as low a concentration as 1 in 1,000,000. In all cases mercury produces depression, irregularity and delirium cordis.

McCrea and Meek (1929) studied the effect of small amounts of mercuric salts upon the automatic and conduction mechanism of the heart. They found that various irregularities of the conduction mechanism occur after intravenous administration. At first there is stimulation of the sino-auricular node attended by an increase in the rate of the heart beat. Later, depression sets in with diminution in the automaticity and susceptibility of the conducting tissue from the sino-auricular node downwards, till fibrillation or paralysis supervenes. Recent work has however shown that the mercury ion in a high state of dilution has a definite stimulant action on animal tissues. A 1 in 1,000,000 concentration of mercuric chloride added to the perfusate distinctly stimulated the isolated mammalian heart and increased its force of contractions.

Gastro-intestinal tract. Mercury, by whichever route it is administered, exercises a selective action on the gastro-intestinal tract and increases the normal peristaltic movements. When soluble salts are administered orally, the effects on the mucous membrane are very severe. Hyperæmia, redness and swelling are immediately produced which commonly end in ulceration of the mucous membrane. The symptoms associated with such lesions are generally diarrhoea with rice water stools, intense pain, tenesmus and passage of blood and mucus with the stool. The insoluble salts like calomel dissolve so slowly and to so limited a degree that the irritative phenomena observed with the soluble salts are not manifested but catharsis is produced. Calomel is widely employed for this purpose and it produces a soft stool without pain or griping.

Mercury has very little action on the ferments of digestion. Large doses may precipitate pepsin. The antiseptic action on the intestine, especially of calomel, is due to retardation of putrefaction and decomposition of foodstuffs by increased peristalsis that hurries the contents down the intestinal canal.

Kidney. The kidneys are stimulated with small doses and diuresis is produced. The mechanism of mercurial diuresis has been explained

on the basis of a mild renal irritation, which favours filtration through the glomeruli and probably hinders reabsorption in the tubules. That there is definite renal stimulation has been proved by the experiments of Goedert (1928) who transplanted the kidneys in novasurol-treated dogs and found that the novasurol-kidney excreted much more urine than the normal kidney. The diuretic effect of the organic mercurials will be discussed later.

Large doses of mercury produce characteristic changes in the kidney in a few hours with consequent anuria, cloudy swelling and necrosis of the epithelium of the tubules. The congestion of the glomeruli and the necrosis of the tubules form the prominent features in post-mortem appearances; the latter may be filled with necrosed cells on which are deposited lime salts and phosphate. The changes are more marked with soluble preparations like the perchloride of mercury than with the insoluble ones.

Central nervous system. The action on the central nervous system is not marked in therapeutic doses. Tremors and giddiness may be temporarily produced. Workers in mercury mines, in mirror works, barometer and thermometer factories are specially liable to develop poisoning symptoms from absorption of mercury. These symptoms consist in great muscular weakness which may develop into hallucination and delirium. Another feature of the nervous affections is a peculiar tremor which involves the hands and arms, and ultimately the legs. Shooting pains along the course of the nerves and joint pains have also been observed. The higher centres of the brain are rarely affected by mercury. In chronic poisoning, signs of hallucination and delusion may point to an affection of the cerebrum but they are extremely rare.

Metabolism. The effects of mercury on metabolism are not fully understood, but in general resemble those of arsenic and phosphorus. Small doses are said to improve the nutrition and lead to acceleration of metabolism of proteins. Prolonged administration may give rise to cachexia. The red blood corpuscles and hæmoglobin content are increased in healthy individuals; in syphilitics there is an initial lowering of the hæmoglobin percentage which is later on considerably increased. In acute poisoning there is glycosuria and disappearance of glycogen from the liver. The effect on the body temperature is negligible.

Fate in the body. Metallic mercury and mercury compounds are readily absorbed from all surfaces including the intact skin. Complex chemical changes are said to occur in the course of absorption. Mercurous compounds and metallic mercury are oxidised and the mercuric salts form soluble compounds with proteins, sodium chloride and alkalies. The absorbed mercury remains in the blood only for a short time but may remain in the tissues for a very long period and continue to exert its specific action by slow ionization and reabsorption.

Excretion. The excretion of this metal takes place mainly through the urine and faeces. Traces are also found in the bile, sweat and saliva; it is not excreted in milk. The form in which it is excreted in the urine is not known.

The rate of excretion varies greatly with the nature of the mercury compound, the method of administration and the diet. The rate of excretion of the water soluble compounds are different from the water-insoluble compounds. Thus with mercury salicylate which is insoluble in water, the excretion gradually increases up to the ninth day, while with a soluble compound the highest rate of excretion is reached on the fourth day. Hence soluble compounds should be given therapeutically in repeated small doses, the total quantity being necessarily smaller than in the case of insoluble ones. Certain insoluble compounds such as yellow mercurous iodide though insoluble probably become water-soluble before being absorbed and this may explain the variability of excretion that may be seen with different insoluble compounds. In addition diet may be an important factor in determining the absorption and excretion of mercury. Under ordinary balanced diet, the daily excretion of mercury in the faeces is much lower than in the urine. But the addition of acid substances greatly augments the rate of faecal excretion. Cole and others (1926) showed that by adding acids to the dietary the faecal excretion of mercury can be increased tenfold, while the urinary excretion is increased only three and a half times.

In general, it may be said that with therapeutic doses excretion declines rapidly and becomes insignificant within a week after the administration ceases. In the case of metallic mercury and colloidal mercury injections, absorption depots are maintained and traces may be excreted intermittently for as long as six months or even longer. A considerable portion of the absorbed mercury however is retained indefinitely in the tissues.

The excretion has been studied clinically by a number of workers and the figures agree in their general features. As the course of urinary excretion is a good indication of the absorption of the metal into the tissues and its mobilisation for therapeutic action, it will be interesting to see how this factor varies with the different mercury compounds in common use. Sollmann's summary of the course of urinary excretion is particularly instructive. He has grouped them into three different types:

1. The completely periodic and remittent type of excretion is met with in all intravenous injections, organic, ionizable, and colloid suspensions. The excretion rises and declines acutely, reaching its maximum in one to two hours, and ceasing practically in 8 to 24 hours. This type applies also to the intramuscular injection of several non-precipitating organic compounds (novasurol, flumerin, saliorgan).

2. The incompletely remittent cumulative excretion is illustrated by the salicylate suspended in oil. The excretion rises and declines rapidly as in the periodic type, but the decline is quite incomplete so that the excretion of the successive injections becomes superimposed, cumulative and even somewhat potentiated.

3. The continuous progressive excretion is obtained when the absorption is nearly continuous so that there is no opportunity for remission. This occurs when depots are established by inunction, and by intramuscular injection of sparingly soluble preparations (gray oil or calomel). The excretion in the after period declines slowly, so that the therapeutic level is maintained for a week or two after the end of the course. Transitions between types (2) and (3) are furnished by oral administration, and by daily intramuscular injections of ionizable compounds, *e.g.*, sodium mercuric iodide.

The fate of absorbed mercury and its distribution in the body tissues is not fully known. Its concentration in the blood, as has already been pointed out, declines rapidly and only minute traces can be detected in it afterwards. Its concentration in the urine approximates to that in the blood. The kidneys usually contain the highest concentration and the largest amount. The liver comes next in order; in cases of intravenous injections of colloidal solutions and dyes, the concentration of the metal in this organ is especially high. The spleen, brains and lungs come next in order. The fat and the muscles contain a low concentration, but the quantity as a whole in the latter is fairly high. Mercury is found in the bones and has been detected by Kolmer in necrotic bone and in the wall of an aortic aneurysm. In the body fluids and in the amniotic fluid mercury is found in fairly good concentrations. It passes through the placental circulation and hence it is claimed that congenital syphilis may be treated by mercurial inunction of the mother. Mercury has been demonstrated quantitatively in the cerebrospinal fluid. Probably mercury is present in this fluid as a freely soluble compound and is present there as a diffusate from the blood. The concentration of mercury in the spinal fluid increases in direct proportion to the number of doses, and the amount of the drug administered.

It has already been pointed out that during the period of active excretion the mercury content of the tissues is high, but after that period there is a drop in the excretion rate; bones and to a lesser extent the liver may act as reservoirs for the unexcreted mercury. This phenomenon is influenced by the pH of the blood and the tissues. Obviously prolonged administration of mercury, especially if the diet is alkaline, results in the deposit in the body of large amounts of mercury which may be released suddenly from the depots by any reaction that lowers the pH of the blood or tissues. This is one of the potential sources of mercury intoxication that have been noticed in ~~subacute~~ or delayed poisoning.

CHAPTER XXXV

THERAPEUTIC USES OF MERCURY

As an antiseptic. Soluble salts of mercury, as has been already stated, are used as skin and local antiseptics. Perchloride of mercury (1 in 1,000) solution is the commonest antiseptic used in surgical theatres and emergency operation rooms. Mercury oxycyanide in 0.2 to 0.6 per cent. solutions have been used as a lotion for wounds. Similarly gauze for surgical dressings has been impregnated with mercurio-zinc cyanide.

As cathartic and intestinal antiseptic. Perchloride of mercury is seldom used internally as it is a strong irritant and corrosive and may give rise to toxic symptoms if the dosage is not properly controlled. In small doses however it is still used by clinicians for its antiseptic and astringent effects on the gastro-intestinal tract. Insoluble mercury salts are however preferred for this purpose. Calomel dissolves so slowly and to so limited a degree that the intestinal irritation and toxic symptoms, commonly produced by the soluble compounds, are not manifested at all. On the other hand, a very mild irritation is produced which stimulates both the large and the small intestines and increases their peristaltic movements, resulting in catharsis. Ordinarily, calomel produces dark-green semi-solid stools in ten to twelve hours. The green colour is due to biliverdin. The appearance of biliverdin in the stools has been considered to be due to the effect of calomel causing an increased flow of bile. This however is an erroneous idea. Numerous investigations with biliary fistulæ have shown that calomel does not increase the flow of bile.

Calomel is commonly used in therapeutics for its antiseptic action and it is one of the most useful and efficient antiseptics known. The antiseptic action is said to be due to the slow formation of mercuric chloride from calomel in the alkaline medium of the pancreatic juice. Following the administration of calomel, the bacterial flora is definitely diminished and this

is reflected in the decrease of the urinary indoxyl. Large doses of calomel may favour bacterial growth by diminishing intestinal resistance.

Calomel is administered either in a single dose of 1 to 5 gr. or more commonly in divided doses of $\frac{1}{4}$ gr. every hour until 2 to 3 gr. are given. The method of giving the drug in divided doses is more favoured, in view of the fact that this method ensures better solution and consequently more efficient action. Grey powder (hydrarg. cum creta) is specially suited for children. The mercurials are of value in obstinate constipation attended with biliousness and they can be conveniently administered at night followed by a saline purgative in the morning.

Calomel should not be used continuously for a long time on account of its systemic actions. This is ordinarily unimportant because any excess is generally excreted before it is absorbed. But conditions in the gastro-intestinal tract, *e.g.*, irritations, ulcerations, may favour rapid absorption and toxic symptoms. It is therefore always advisable to follow calomel after 6 hours by a saline purgative.

As a remedial agent in syphilis. The most important therapeutic use of mercury is in the treatment of syphilis. It is the classical remedy and has been in use from the time when syphilis was first recognised (1495). Until the discovery of arsphenamine in 1905, mercury held a place above all other remedies. With the knowledge of the antisiphilitic properties of arsenic and bismuth, mercury has fallen into the background and little attention has been paid to it in recent years though it is still used as an adjunct to arsphenamine treatment.

Effects of mercury in syphilis. Mercury is directly fatal to the treponema *in vitro*, and is effective in the local prophylactic treatment. With therapeutic doses however the concentration of mercury in the blood is far too low to be actively parasitocidal. If sufficiently prolonged treatment is carried on with mercury alone, permanent cure may be obtained. This has been proved by Kolle in experimental syphilis of the rabbit but it is not safe to rely upon it clinically.

The action of mercury in syphilis is similar in nature to arsphenamine and bismuth but it is distinctly slow and progressive. The number of treponemas in the primary lesions is greatly diminished after the administration of mercury. The superficial secondary lesions, *e.g.*, eruptions, mucous patches, clear up in the majority of cases. The tertiary lesions are checked and arrested but may not disappear completely. If treatment is stopped too early the disease again becomes active and more resistant to treatment. Relapses after mercury treatment are more frequent than with arsphenamine and bismuth and they occur soon after the active medication is discontinued.

Mode of action of mercury in syphilis. The mechanism of antisyphilitic action produced by mercury is not understood. Though the metal has direct lethal effects on the treponema, the concentration necessary to produce such lethal effects is never reached in the blood in doses which do not exceed the tolerance of the patients. Various theories have been advanced but none of them can explain the action satisfactorily. These include (1) direct toxicity to the parasites, (2) formation of antibodies or immune substances, (3) increased resistance by other factors, (4) increased susceptibility of the parasites to the protective mechanisms and (5) combination of all these factors.

Value of mercury in comparison to arsphenamine and bismuth. Syphilis can be promptly checked by chemotherapy, especially by the arsenic derivatives, almost as rapidly by bismuth, and somewhat more slowly by mercury, so that the treponema disappears from the lesions and the symptoms subside completely, at least in the early stages. As in other spirochaetal infections, recurrence is common unless the treatment is continued for some time. The permanent clinical cure of syphilis requires continuous energetic treatment for at least 2 years. Mercury, by whatever method it is administered, tends to produce cumulative effects and therefore periods of treatment must always be alternated with periods of 'rest'. Usually the drug is given for a period of 8 weeks, and then rest for one month is given. This process cannot be continued beyond a certain point, because symptoms of mercurial poisoning appear. To avoid symptoms of poisoning and to get the maximum effect,

it is best to alternate several antisyphilitic remedies instead of pushing unintermittently the same metal. This sort of alternation of the two drugs gives 'rest' to the patient without giving any respite to the parasites; the therapeutic effect is thereby enhanced by permitting higher dosage and probably also by attacking the parasites from several angles. Arsphe-namine, and mercury or bismuth are therefore given on alternating courses. Arsphe-namine is more rapid in action and is therefore used at the beginning of a course whereas mercury effects appear to be more thorough and more persistent. Bismuth is intermediate between mercury and arsphe-namine in rapidity and perhaps in power. Bismuth causes less pain on intramuscular injection and is less liable to set up serious stomatitis. On this account, it has practically displaced mercury in venereal diseases clinics.

Prophylactic use of mercury. Mercury has been used as a prophylactic remedy in syphilis for a long time. It often prevents the onset of primary and secondary lesions, if applied locally before the treponema have penetrated, *i.e.*, within 4 or at the most 8 hours after exposure. It has no preventive action 12 hours after exposure. The usual procedure recommended is to cleanse the site of the suspected infection with soap and dress the part with an ointment containing 33 per cent. of calomel or 0.3 per cent. of corrosive sublimate (Neisser-Seibert ointment). Schlossberger (1931) found that the prophylactic substances containing mercury prevented the dissemination of the spirochaetes through the scarified skin of mice only if the applications preceded that of the treponema; they were totally ineffective if applied even immediately after inoculation with the organism. This suggests that prophylactics containing mercury do no real good but may do harm by preventing the recognition of infection. This view however has not been supported by other workers who believe that mercury has got some prophylactic value if applied within 4 hours after exposure.

As a diuretic. All mercury compounds during their excretion stimulate the renal epithelium and produce a distinct diuretic effect. This diuretic effect is particularly marked when

there is oedema of the tissues. This property of mercury was known long ago and clinically made use of in the form of Guy's pill which is a combination of blue pill (*pilula hydrargyri*), with digitalis and squill. The diuretic effect of calomel was however unreliable and the diarrhoea set up during its administration was a very objectionable feature to the patients. Within recent years a number of stable organic mercury compounds have been prepared (see detailed description later on) which are soluble in water, practically non-irritant and non-toxic in therapeutic dosage, and can be used both intramuscularly and intravenously. Salyrgan (*Mersabyl*) and Novasurol (*Merbaphen*) are two well-known members of this group.

In cases of ascites following malaria and kala-azar, organic mercurial preparations have sometimes produced marvellous results. The excretion increases within 2 or 3 days of the administration of the drug and this increase is maintained for 6 to 7 days. These preparations have also been used in oedema following anaemia and hookworm disease. In the endemic ascites of the tropics, so commonly met with in Bengal and Bihar, novasurol and salyrgan have been given a trial in the Carmichael Hospital for Tropical Diseases. Megaw was of opinion that this condition was the end-result of bacillary dysentery and similar intestinal disturbances. Whether bacillary dysentery or avitaminosis is the principal factor concerned has not been determined, but experiences of various workers both in the School of Tropical Medicine and in the hospitals of various provinces in India definitely indicate that it is worth while to give mercury preparations a fair trial in these conditions.

In septicæmic condition. The antiseptic action of mercury has been utilised in the treatment of various septic processes, *e.g.*, septicæmia, pyæmia, erysipelas, puerperal fever, and septic sore-throat. Injections of mercury benzoate, 10 c.cm. of 1 per cent. solution have been given in many septicæmic conditions to disinfect the blood and tissues.

Young and Hill (1924) gave perchloride of mercury in doses of 2 to 5 mgm. per kilo. body weight in 1 per cent. solution in water, successfully in puerperal sepsis. Dudgeon (1926) tried perchloride in 330 cases of acute bacterial infections

such as influenza pneumonia; 5 c.cm. of a 1 in 1,250 solution of normal saline was given as the initial dose, repeated if necessary in 12 to 24 hours, according to the condition of the patient. Thrombosis, diarrhoea, stomatitis and nephritis were some of the complications encountered in his series of cases. Pritchard (1927) treated pneumonia both lobar and lobular, acute staphylococcal infections, chorea and subacute rheumatism, chronic infective arthritis of undetermined origin and encephalitis lethargica with injections of mercuric chloride (1/64 to 1/16 gr. in 8 to 10 c.cm. of normal saline) with fairly satisfactory results. Mercurochrome is another mercury preparation which has been widely used in septicæmic conditions. Encouraging results have been reported in puerperal sepsis. Following the routine use of mercurochrome intravenously in lobar pneumonia the mortality rate in Puerto Castilla Hospital, Honduras, was lowered by 12½ per cent. in 1925. Doses varying from 1.5 to 2 c.cm. of a 1 per cent. solution per 100 lb. body weight were usually given. The use of mercurials in septicæmia is however not unattended with danger. Reactions of the nature of colloidal shock have been reported which may lead to disastrous consequences.

Skin diseases. Mercury has been applied externally in various skin diseases of parasitic origin—such as itch, ulcers, condylomata and ulcers of syphilitic origin. In all these conditions, mercury acts as a disinfectant and irritant. Ointments containing mercury in metallic form such as unguentum hydrargyri are the least irritant of all. Mercury oleate, yellow oxide, red oxide and ammoniated mercury are also commonly used. As a lotion, black wash or yellow wash is the common external application; as a dusting powder calomel may be used on ulcerating surfaces, *e.g.*, in corneal ulcers.

Gonorrhœa and gleet. Mercury has been used as a lavage in urethritis, a lotion of 1 in 4,000 to 1 in 2,000 of mercuric chloride being commonly employed. Mercurochrome has been used intravenously in many cases of acute gonorrhœal infection. Redewill and Potter (1920) reported a high percentage of apparent cures within a very short time. Cases complicated with epididymitis, synovitis, arthritis, etc., have also been

successfully treated. Cystitis and pyelitis of gonococcal origin have been relieved.

Asthma and hay fever. Mercury has been found useful by some observers in hay fever, asthma and bronchiectasis. Injections of mercury salicylate, 1 per cent. suspension in oil, have been given for relief of the attack; $\frac{1}{2}$ gr. of calomel has also been used during the premonitory stages of an attack of asthma. These observations, however, have not been widely corroborated.

Bilharziasis. Bilharziasis has been treated with intravenous injections of mercuric chloride. In the early stages of the disease where anaemia is not marked mercurochrome is reported to have given satisfactory results.

MODES OF ADMINISTRATION

Mercury is administered chiefly by (1) inunction, (2) the mouth, (3) intramuscular injection, and (4) intravenous injection. All these methods have their special advantages and disadvantages.

Inunction. Mercury when triturated with fat forms a colloidal suspension which is rapidly absorbed when rubbed on the skin. Histological examination of the skin after inunction with mercury shows that the mercury globules do not enter the epidermis, but that they penetrate deep into the sweat glands and hair follicles and from there they are absorbed. It is a fairly effective method of administering mercury. Undesirable local and gastro-intestinal effects are not noticed and it is easy to avoid serious overdosage. The disadvantages are that it is time-consuming and disagreeable and the exact amount absorbed cannot be accurately determined.

In the United States Pharmacopœia there are two preparations, 'Stronger mercurial ointment' (50 per cent.) and 'Milder mercurial ointment' (30 per cent.) which are used for inunction purposes. An inunction course usually consists in inunctions being given six times a week for four to six weeks. This is followed by a rest for a month, and then the treatment is repeated.

Oral administration. The oral route is the easiest method of administering drugs but it is not suitable in the case of

mercury and has now been largely replaced by other methods in adults. In the case of children, this method is still retained for the sake of convenience. Considerable quantities of mercury can be absorbed from the gastro-intestinal tract even when the insoluble mercurous compounds are administered. This is proved by the incidence of salivation and the urinary excretion which is quite as high as with inunctions and intramuscular injections. The gastro-intestinal irritation is the serious drawback which has restricted oral administration. The patient also cannot be kept under control and the rate of absorption cannot be determined with any degree of accuracy.

Mercury can be given orally either as a solution of a soluble mercury salt or as a pill containing an insoluble mercurous salt or as metallic mercury. The usual preparations used, in order of preference are *Hydrargyrum iodidum flavum* (Proto-iodide) dose 0.01 to 0.05 gm. ($\frac{1}{4}$ to 1 gr.); *Hydrargyrum cum creta*, 0.05 to 0.2 gm. (1 to 3 gr.); *Hydrargyrum subchloridum*, 0.05 to 0.1 gm. *Hydrargyrum chloridum corrosivum*, 0.002 to 0.004 gm. (1/32 to 1/16 gr.). To prevent local corrosion, mercuric chloride is administered with excess of potassium iodide or in milk.

Rectal administration, fumigation, inhalation of mercury vapourized at room temperature are no longer used in practice.

Intramuscular injections. Three classes of preparation are used for intramuscular injections: (1) water-soluble ionizable compounds, (2) water-soluble non-ionizable compounds, and (3) water-insoluble compounds.

Water-soluble ionizable compounds. Lewin in 1867, first injected mercury intramuscularly and used a watery solution of mercuric chloride. Mercuric chloride (1 c.cm. of 1 per cent. solution) injections are very painful and should not be used. In general, all these salts are objectionable because pain and sloughing of tissues may follow, though some salts like the benzoate, succinimide, cyanide, biniodide (double salts) cause comparatively less pain than mercuric chloride.

Basic mercuric salicylate is insoluble in water but is soluble in sodium chloride solutions or alkalis. It is given suspended in oil but is absorbed as rapidly as the water-soluble salts. It causes very little pain.

Water-soluble non-ionizing compounds. These include novasurol, nalyrgan and mercurisol. The antisyphilitic action of the first two is practically negligible. They cause very little local irritation and are not toxic in therapeutic dosage. The absorption is very rapid and

fairly complete. These are used as diuretics and will be referred to again.

Water-insoluble compounds. These compounds are usually given suspended in oil. Although these are highly effective, they are now practically out of use. Their absorption is slow, since they must first be converted into soluble compounds; but when the injections are repeated, the absorption from the multiple depots becomes cumulative and uncontrollable. Stomatitis is a frequent complication. Calomel 10 per cent. suspension in olive oil in dosage of $\frac{1}{2}$ c.cm. weekly to 1 c.cm. twice weekly is used. Calomel has also been injected as a 5 per cent. suspension with 2 per cent. carbolic acid or creosote or camphoric acid. Metallic mercury, finely divided, as the 'gray oil' (oleum cinereum) has been injected in 40 per cent. solution, $\frac{1}{2}$ c.cm. weekly.

Intravenous injections. Intravenous injections of mercury were introduced by Bacelli with the idea of securing a maximal concentration of mercury in the blood without any of its unpleasant and untoward local actions. These however have not attained any degree of popularity. Preparations for intravenous injections may be conveniently studied under two groups.

(1) **Ionizable salts.** Mercuric chloride, oxycyanide, benzoate and the double iodide have been administered in 1 per cent. solution in doses of 1 to 3 c.cm. daily or every second day. With mercuric chloride it is advisable to add 3 per cent. of sodium chloride to the solution. The therapeutic results in syphilis following the administration of these compounds are not at all encouraging, at least no special benefit is reported by this method. Strickler (1928) who tested the efficacy of this method found no change in the Wassermann reaction after 37 intravenous injections of the benzoate. The chief difficulty appears to be that the metal is rapidly excreted and does not maintain a concentration in the blood sufficiently high to be lethal to *T. pallidum*. The study of the urinary excretion proves this point conclusively. In a series of experiments, Lomholt found that the excretion rose to a peak in one or two hours after each injection, which is about ten times the average level after intramuscular injections.

(2) **Organic compounds.** Novasurol, salyrgan, mercurosol have been used to a much greater extent than the ionizable mercury salts. As has been already stated, these compounds are not very effective in syphilis and their chief use is in connection with the production of diuresis. With these compounds, as with ionizable salts, urinary excretion of the metal proceeds at a rapid rate within an hour or two, and declines promptly, reaching an insignificant level within 8 hours after injection. These therefore suffer from the same disqualification as the other group. Moreover, novasurol and mercurosol

produce diarrhoea and dysentery-like symptoms in some patients. Salyrgan is not reported to have caused any untoward symptoms. The mercurial dye flumerin occupies a peculiar position amongst the organic mercury compounds. Like other dyes, it tends to form colloidal absorption products with proteins. In experimental rabbit syphilis, promising results have been obtained but it is not superior to the ordinary mercurial treatment.

Apart from these two groups, mercury in colloidal form has also been injected intravenously. A true colloidal solution of mercuric sulphide known as *Mersufol* (2 per cent. solution) is available in the market. This preparation has the advantage over others in that the excretion of the metal is not very rapid, in fact a good deal of mercury is retained, even after four weeks following its administration. This would have proved quite a useful preparation but for the fact that considerable salivation is produced in the patients and the mobilization of the metal cannot be controlled. *Mercodel* is another preparation which is not colloidal but is a water suspension of fine sub-microscopic globules of mercury to which a little glucose is added. With doses larger than 200 mgm. per week, it is an effective drug but serious stomatitis is a frequent complication. Smaller doses, though free from undesirable side-effects, are useless.

Disadvantages of intravenous administration. It will be seen from the above that intravenous administration of mercury is not the method of choice and is not as effective therapeutically as the intramuscular method. Most of the compounds irritate the veins at the site of injection and tend to produce fibrosis and occlusion of the vein. They also present some danger of embolism and colloido-clastic shock. Urinary excretion studies indicate that the high concentration reached by intravenous injection is of too brief a duration to be useful in chemotherapy and the maintained level is generally too low, even with daily injections. The organic and inorganic preparations are presumably fixed up in the tissues and remain inactive to a large extent. The colloidal compounds are probably enmeshed in the reticulo-endothelial cells, forming depots from which active mercury is absorbed and circulates for long periods but the absorption is variable and is uncontrollable, giving rise to severe untoward effects in most cases.

CHAPTER XXXVI

TOXIC EFFECTS OF MERCURY

Acute toxic manifestations are produced, generally from mercuric chloride poisoning. The immediate effects are due to irritation, superficial corrosion and coagulation of the proteins of the mucous membranes. Salivation, swelling, burning and discolouration of the mucous membrane of the mouth and pharynx are constant features. Abdominal pain and distress with vomiting of bloody mucous shreds are also met with. Twenty-four hours later, mercurial stomatitis develops but this is not very severe. Later, the large intestine and kidneys become involved. The urine becomes scanty and highly-coloured with copious albumin and casts. Anuria has occurred in some cases followed by death within a week. If the nephritis is not fatal, a membranous colitis develops with ulceration and hæmorrhage. Hepatic degeneration may supervene. Death occurs from circulatory failure in some cases.

Post-mortem examination shows the mucous membranes of the mouth, pharynx, glottis, œsophagus and stomach to be corroded and extremely congested. In the colon, necrosis and ulceration and consequent congestion are met with. The kidneys show signs of acute nephritis and the liver cells are degenerated in some cases.

The symptoms of acute mercurial poisoning are not produced in therapeutic doses of the drug and are therefore not very important from the clinical standpoint. A sort of subacute mercurial poisoning is the usual outcome of prolonged treatment. The symptoms which have to be guarded against by the physician in such cases are of a milder nature and consist of localised chronic inflammations, especially stomatitis, colitis, nephritis, etc. The stomach and large intestines are usually not involved as in the case of acute poisoning.

Stomatitis is usually the earliest symptom of subacute and chronic mercurial poisoning. It occurs constantly by whichever route mercury is administered. A metallic taste in the mouth, soreness of the gums and salivation are the primary manifestations. If not noticed in time and if the drug is pushed further, blackening of the gum margins, loosening of the teeth, uncontrollable salivation and later, fatal ulceration of the mouth may supervene. The kidneys are specially susceptible to mercury and therefore albuminuria is a common finding. The damage however is not as marked as in cases of acute poisoning and tends to involve the interstitial cells more than the glomeruli. Long-continued exposure to relatively small doses leads to a slow and insidious development of chronic poisoning, usually with some stomatitis and renal irritation, but with additional nervous and nutritional disturbances. Cachexia with anæmia and malnutrition are found together with psychic irritability, tremors and restlessness.

Treatment of mercurial poisoning. The prognosis in cases of acute mercurial poisoning is grave unless prompt emesis is resorted to within 15 minutes of the administration of the poison. Mercury is rapidly fixed in the mucous membrane of the stomach and once it gets fixed, the antidotes (milk, calcium sulphide, thiosulphate, etc.) naturally cease to react. Lavage is sometimes helpful by removing the mercury which may remain free in the stomach at the time. The simplest antidote consists of three raw eggs in a quart of milk followed by gastric lavage. The local antidotes must be followed by an emetic to expel any poison which might remain unabsorbed. Administration of glucose and alkalies is useful and hot packs in the kidney region may help in soothing the renal irritation. Sodium thiosulphate has been advocated intravenously but is not very satisfactory.

In subacute cases, stomatitis and colitis are the symptoms to be attended to. Stomatitis is most effectively prevented and treated by hygiene and care of the teeth. Septic conditions about the gums are especially liable to cause poisoning and should be attended to before mercury treatment is started. When stomatitis is very severe, mercury should be stopped and

mouth washes and gargles of an antiseptic nature should be prescribed. Hydrogen peroxide, potassium chlorate, potassium permanganate are all useful and should be used several times a day. The gastro-intestinal troubles usually yield to sedatives such as chalk and bismuth. Stimulants, whenever necessary, should be given.

Cases of chronic mercurial poisoning seen in workers in mercurial mines, etc., cannot be much improved even with vigorous treatment. In these cases, prevention and protection against unnecessary exposure are more important.

PREPARATIONS OF MERCURY

The preparations of mercury which are recognised in the British Pharmacopœia are too well known to require any detailed description. In recent years attempts have been made to improve mercurial therapy and a number of organic compounds have been prepared. As these compounds are coming into prominence in the treatment of various conditions commonly met with in the tropics, it will be worth while to discuss them in some detail.

MERCUROCHROME 220

Mercurochrome is disodium-dibromo-hydroxy mercury fluorescein, and was prepared in 1920. Dose 0.002 to 0.003 gm. per kilo; in man 2 to 5 gr. (0.13 to 0.32 gm.). It is given intravenously in the form of 0.5 per cent. solution in distilled water. Though solutions of 1.0 per cent. and of higher strength have been recommended, they are not desirable. Mercurochrome 'sterules' containing 0.2 gm. dissolved in 40 c.cm. of water for intravenous use are on the market.

Pharmacological action. Mercurochrome has a well-marked disinfectant action and is largely employed as a general antiseptic in surgery. A 2.5 per cent. solution is useful for surface lesions, for painting on the mucous membranes or for injection into sinuses. Given intravenously in animals, mercurochrome causes no marked reaction if a 0.5 per cent. solution is used. Stronger solutions produce a fall of blood pressure. Administration of 0.2 mgm. per gm. weight of mice produce immediate death of the animal. Small doses are therefore recommended in man and deaths have occurred with 8 to 15 c.cm. of a 1.0 per cent. solution. It is absorbed into the blood and is excreted in the gastro-intestinal tract, in the bile and by the kidneys. It is, for this reason, used as an urinary and biliary antiseptic. Bile collected after intravenous injections is said to have definitely bactericidal properties, but this has not been proved. Large doses irritate the kidneys as well as the intestines and produce diarrhœa. Kofoid and Wagner (1925)

found that 1 in 11,000 of mercurochrome has a lethal effect on cultures of *E. histolytica*; 1 in 3,500 inhibits the growth of *B. coli* in nutrient broth, 1 in 8,000 inhibits growth of hæmolytic streptococci.

Therapeutic uses. Mercurochrome is recommended in all forms of bacterial diseases. It has been used in gonorrhœa, gonorrhœal arthritis, cystitis and pyelitis with good results. As a vesical antiseptic 1 per cent. solution can be used for lavage without causing any pain. It is very penetrating and has a low toxicity. Young and others (1921) obtained a cure rate of 75 per cent. in chronic cystitis with this drug. The routine method of giving vesical injections is to give 30 c.cm. of a 1 per cent. solution, stronger solutions should be used with great caution. A 5 per cent. solution as a urethral lavage can be relied upon to clear up gleet in most chronic cases, and great improvement has been noticed after treatment. Gonorrhœal arthritis is said to be favourably influenced by intravenous medication for which 10 c.cm. of a 1 per cent. solution is generally recommended. It has also been tried in plague, pneumonia, Malta fever, puerperal septicæmia, syphilis, typhoid and tuberculous affections. Mercurochrome has been tried in the treatment of intestinal protozoal infections. It is given by the mouth in 1 to 5 gr. (0.13 to 0.23 gm.) doses three times a day, the drug being continued for 2 or 3 weeks. It is germicidal and penetrating and forms no precipitate with the proteins. It is usually given in keratin-coated capsules and no harmful or distressing effects have been observed. Encouraging results are also said to have been obtained in amœbic dysentery as well as in *Giardia* and *Chilomastix* infections. The stool changes into a deep mahogany colour and must be kept thus so long as the drug is administered. Rarely, the drug produces intestinal cramps and nausea.

Mercurochrome has also been used in the form of colonic irrigations, a 5 per cent. solution being injected slowly into the rectum in amœbic dysentery. In ulcerative colitis lavage with 6 to 8 ounces of a 0.3 per cent. solution has given good results. It has been used against leprosy for checking rapid retrogression, in the treatment of ulcers following on disintegrating tubercles and in healing neurotropic ulcers, weekly injections of 1.0 per cent. solutions are generally given. Good results have followed by combining it with chaulmoogra oil esters. It has also been tried in malaria, especially the chronic forms, but has no effect in this disease. In relapsing fever 15 c.cm. of a 1.0 per cent. solution produced a fall of temperature and no further recurrence of attacks.

Tootell (1926) tried the drug in the early stages of schistosomiasis where no serious complications were present, and obtained good results. The author tried mercurochrome in filariasis but found it to be useless. In yaws, marked improvement has been obtained by two injections of 5 c.cm. of a 2.5 per cent. solution. The lesions healed quickly.

Given intravenously the drug is claimed to have given good results in general septicæmia, puerperal fever, diffuse cellulitis, lobar pneumonia, typhoid, pyelitis and many other conditions. The maximum dose is 10 c.cm. of a 0.5 per cent. solution in saline. The rigors which follow intravenous injections may be greatly modified by keeping the patient warm during and after treatment and by giving 10 gr. of aspirin with hot tea immediately after injection. Intravenous injections of mercurochrome with glucose are said to be less toxic than mercurochrome alone, but it is insisted that the glucose mercurochrome mixture should be made immediately before use. While some workers have found the drug to be very effective in septicæmia, others find it has little or no effect. Human blood treated with mercurochrome (1 in 40,000 to 1 in 10,000) has no bactericidal power for staphylococci and hæmolytic streptococci. Bile from rabbits treated with 5 mgm. of mercurochrome showed no bactericidal power for *B. typhosus*. It has been suggested that the remarkable clinical improvement in some septicæmic patients is brought about by an auto-immunisation process initiated by severe constitutional symptoms which may follow the injection of the drug. The results would thus be analogous to protein shock. In secondary syphilitic manifestations injection of 5 to 10 c.cm. of a 2.5 per cent. solution has given good results, but the effects are inferior to arsphenamine or bismuth.

Toxic effects. The toxicity of different samples varies. Salivation, stomatitis and severe diarrhoea, commonly nausea and vomiting, rose-coloured stools, rigors and rise of temperature may occur after large doses. The kidneys may be irritated and albumin may occur in the urine. The margin between the therapeutic and toxic doses of mercurochrome is variable and small. As a rule no gastro-intestinal disturbances are produced till the drug has been continued for a week. Idiosyncrasy and hypersensitiveness to mercurochrome may rarely occur. Such patients excrete a greater quantity of mercury by the saliva and the gastro-intestinal tract than by the kidneys. In these individuals most of the drug appear to be excreted by the gastro-intestinal tract and not by the kidneys and signs of mercurial poisoning are quickly produced.

A number of other preparations of mercury and dyes have been produced, e.g., *mercurochrome 565* which is a mercury derivative of rose-benzol 3B and benzurine. It is still in the experimental stage.

FLUMERIN

Flumerin is the disodium-hydroxy-mercuri-fluorescein. It is a red odourless powder, somewhat hygroscopic, containing 83 per cent. of mercury. It is soluble in hot water, about 1 in 10, but insoluble in alcohol, ether or chloroform.

Pharmacological action. Flumerin is an antiseptic. It is far less toxic than other compounds when given intravenously in animals. It is liable to produce irritation of the kidneys on repeated administration. It is tolerated by rabbits in doses which are about 8 to 20 times higher, calculated according to mercury content. According to some workers, when given intravenously in man in doses of 3 mgm. per kilo. body weight, the drug causes disappearance of the spirochaetes from primary and secondary syphilitic lesions. The influence on the Wassermann reaction was also encouraging, rendering one-half of the positive cases negative within a short time. In tertiary syphilitic lesions the resolution of the lesion and the disappearance of a positive Wassermann reaction were brought about in a majority of the cases. Snodgrass (1924) also obtained improvement of gross secondary lesions within one week of the administration of the drug. The influence on the Wassermann reaction was not a lasting one. Great toleration to the drug was noted. Moore and Wassermann (1924) suggest the combined use of arsenobenzol and flumerin. They advise a course of 8 injections of arsenobenzol at 5 to 7 days intervals, then one week later 12 flumerin injections every other day; this is immediately followed by 6 injections of arsenobenzol and one week later by 16 injections of flumerin.

Toxic symptoms have been noticed with the drug. These are salivation, and gingivitis and are not generally fatal. Damage to the kidney is sometimes liable to occur, especially in cases where there are pre-existing kidney lesions.

The dosage for adult males is from 0.2 to 0.3 gm. given in 2 per cent. solutions intravenously at bi-weekly intervals, the average number of injections necessary being 8 to 10. In no case should more than 0.3 gm. be given at a time for fear of toxic symptoms supervening.

NOVASUROL

Novasurol is also known as merbaphen; it is the double salt of sodium mercuri-chlorphenyl oxyacetate with diethyl barbituric acid (barbital). Novasurol occurs as a white crystalline powder, soluble in cold water and contains about 34 per cent. of mercury.

Pharmacological action. Novasurol was originally intended to be an antisymphilitic remedy but has come to be used as a diuretic. It has the advantage over mercurous chloride that it is soluble in water and can be advantageously given intramuscularly or intravenously. When given intramuscularly it is excreted in the gut and doses higher than 2 c.cm. are liable to cause gastro-intestinal irritation with profuse watery stools.

The action of novasurol on the kidneys is important, since it has been extensively used in cases of nephritis with oedema. The beneficial effect is more marked in oedema due to myocardial insufficiency than in

cases of nephritis, where it is contraindicated. The exact mode in which novasurol brings about diuresis is not known. It is believed by some to be the result of a combined action on the kidney and extrarenal tissue. Bohn (1923) believed that extrarenal mobilization of fluid is the most important factor in the diuresis produced. Jackson (1928) showed that changes occur in the volume of the kidney after administration of novasurol and he considers that the diuretic effect is related to the vascular changes brought about in the kidney, possibly causing greater contraction in the efferent than in the afferent glomerular capillaries.

Toxicity. Johnstone and Keith (1928) found that in rabbits doses of 0.7 c.cm. per kilo. killed the animals within a few minutes and death was assumed to be due to ventricular fibrillation or to a direct effect on the vital centres in the medulla. A dose of 0.168 c.cm. per kilo. was lethal. Repeated doses were consistently toxic and the kidneys showed characteristic degenerative changes. These consisted in the early stages of swelling of the epithelium, specially of the proximate convoluted tubules. Larger doses produced extensive degeneration involving wide areas.

In man, toxic symptoms have occurred after novasurol. In mild cases, certain disagreeable symptoms such as headache, vertigo, nausea, vomiting, stomatitis, diarrhoea, fever and rash are seen. These symptoms are generally mild and clear up with the discontinuance of the drug. In certain cases hæmaturia has occurred; death from the effect of novasurol is also on record.

Therapeutic uses. It is useful in dropsies due to cardiac and cardiorenal diseases. It has been recommended in passive congestion of the kidney's, in nephrosis, and in arteriosclerotic and idiopathic contracted kidney. Ascites due to cirrhosis of the liver and Banti's disease is not usually benefited by the drug. As a diuretic 0.5 to 1 c.cm. of a 10 per cent. solution is advised. Rowntree and his co-workers (1925) advise simultaneous administration of ammonium chloride with novasurol, to improve the diuresis. As an antisyphilitic remedy the initial dose is 0.75 c.cm. or 1 c.cm. of 10 per cent. solution injected intramuscularly once or twice weekly, later the doses should be increased to 2 c.cm. More recently, 1 c.cm. of a 10 per cent. solution of novasurol, mixed with the required dose of arsphenamine has been used intravenously in syphilis. This is repeated every 5 days for about 8 injections.

SALYRGAN

This is another member of the organic mercury compounds which has been used in recent years very extensively in cardiac or renal oedema, to produce diuresis. It is a complex synthetic mercurial prepared by the action of mercury acetate and methyl alcohol on

salicyl-allyl-amido-acetic acid and subsequent conversion to the sodium salt. The mercury content is about 40 per cent. in non-ionizable form. It is a white crystalline powder, soluble 1 in 1 of water. It has been demonstrated to have spirochaetocidal properties. The diuretic property of the drug is well known.

Salyrgan has been used in a great variety of conditions: (1) Cardio-renal oedema, (2) nephrosis, (3) malignant conditions with ascites, (4) cirrhosis of the liver, (5) tubercular peritonitis, (6) pleurisy with effusion, (7) malignant conditions with chylous pleural effusion.

The advantages claimed for the drug are that stomatitis and proctitis, common with merbaphen, do not occur with salyrgan. Brunn (1924) reports diuresis of from 3 to 4 litres after the use of the drug in 27 patients with oedema as a result of various cardiac disorders. No ill effects were seen and no increase of albumin in the urine was noticed. Herszky (1925) observes that salyrgan is effective occasionally, when merbaphen fails and he has not found any single case of mercurial intoxication. Jacobs and Keith (1926) suggested the use of ammonium chloride and nitrate with mercurials in order to raise the diuretic response.

The mechanism of salyrgan diuresis is difficult to explain. Richards (1925) believes that intraglomerular pressure, which is so important in urine formation, is under a very delicate balance of control in case of cardiac or cardiorenal oedema and that the tension on the afferent artery is probably not more important than the tone of the efferent vessel in maintaining this glomerular pressure. It is probable that the diuretic effect of salyrgan is due to this vascular response with an increase of pressure in Bowman's capsules. Jackson (1926) showed that respiration is accelerated, the blood pressure rises slightly and the kidney volume decreases. He thinks that the action of mercury preparations is on the vascular structure of the body and that the diuresis is related to a vascular response.

Mercuriol. Mercury nucleinate is the organic compound of mercury with nucleinic acid, containing about 20 per cent of mercury. Mercuriol has a powerful antiseptic property. It is markedly bactericidal and does not coagulate albumin which ensures better penetrability and intimate contact with organisms. It resembles in general, the action of soluble mercury compounds. It is used as a local antiseptic and as an antisyphilitic remedy. Dosage is 0.08 to 0.12 gm. by the mouth in the form of tablets.

Mercurosal. This compound is the disodium-hydroxy-mercuri-salicyl-oxy-acetate, containing from 43 to 44 per cent. of mercury. Mercurosal is a white amorphous powder. It is soluble in about 10 parts of water. It is fairly stable in aqueous solutions and should be kept well-stoppered and protected from air. It is claimed to be a relatively non-toxic compound and that it is eliminated without producing any

damage to the kidneys and at the same time, its toxicity is much lower than either mercuric chloride or salicylate. It does not coagulate albumin.

The dosage recommended in syphilis is 0.05 gm. dissolved in 2 c.cm. of water every fourth or fifth day, a total of ten or twelve injections being necessary.

Mergol. It is a mixture of 1 part of mercuric cholate and 2 parts of albumin tannate. It is put up in capsules each capsule containing approximately 0.15 gm. of mergol, equivalent to 0.05 gm. of mercuric cholate and 0.1 gm. of albumin tannate. Mergol contains about 44 per cent. of mercury.

Mergol is said to pass through the stomach unchanged and is decomposed in the small intestine from whence the mercury is quickly absorbed into the circulation. The main channel of excretion of mercury is through the kidneys. It is employed in the treatment of syphilis, given in doses of one capsule three times a day after meals gradually increased to 2 capsules five or six times a day.

Meroxyl. It contains 50 per cent. of sodium-2:4-dihydroxy-3:5-dihydroxymercuri-benzophenone sulphonate with foreign matter consisting of ammonium-dihydroxy-benzophenone-2-sulphonate, sodium acetate and water. The mercury content varies between 26 to 29 per cent. Young and others (1923) recommend meroxyl as a local antiseptic for dressings and irrigation of wounds and for gonorrhoeal cystitis and abscesses a 0.1 per cent. solution is preferred as an antiseptic. For prophylactic treatment of urinary infection 0.5 per cent. solution should be used. Solutions of 2.5 per cent. or stronger form a gel on standing.

Metaphen. This is diacetoxy-3:5-mercuri-4-nitro-2-cresol. It contains about 58 to 60 per cent. of mercury. Metaphen is a yellow substance, insoluble in water. It is a powerful germicide. Rabbits experimentally infected with *staphylococcus aureus* are beneficially influenced by the drug 48 to 72 hours after the infection. On the intact skin and mucous membrane it is stated to be relatively less toxic than other organic preparations. White rats can tolerate doses of 0.03 gm. per kilo. body weight when injected intramuscularly and 0.004 gm. per kilo. when given intravenously. For disinfectant purposes and for sterilising the skin solutions of 1 in 5,000 to 1 in 1,000 are prepared with the aid of caustic soda; for ophthalmic purposes solutions of 1 in 10,000 to 1 in 5,000 are preferred. Urethral lavage should be done with solutions of 1 in 10,000 to 1 in 5,000.

2-Myristoxymercuri-3-hydroxybenzaldehyde. This is an organic preparation of mercury prepared by Henry and Sharp of the Wellcome Research Laboratories. This preparation is easily soluble in hydnocarpus oil and is practically non-toxic. Dissolved as a 0.25 per cent. solution in hydnocarpus oil, the preparation is known as 'avenyl'. Mair

(1926) found that hydnocarpus oil alone produced no effect on the Wassermann reaction and he was able to give as much as 10 c.cm. of this compound twice weekly for 15 doses without producing toxic symptoms of any kind. Of 30 leprosy patients with positive Wassermann reactions treated with avenyl, sixteen were rendered negative. In a further paper Lloyd, Muir and Mitra (1926) state that they have never encountered unpleasant reactions or toxic effects from the use of avenyl. Avenyl is therefore particularly suitable in leprosy patients with a syphilitic taint. In these cases, organic arsenicals are unsuitable and may frequently give rise to toxic manifestations and check the progress of leprosy treatment.

PART IV

REMEDIES USED AGAINST BACTERIAL DISEASES

CHAPTER I

GENERAL CONSIDERATION

The bacteria are minute unicellular masses of protoplasm which are devoid of chlorophyll and definite nuclei. The dimensions of most of the cultivable forms of bacteria are of the order of low multiples or sub-multiples of μ or $1/25,000$ of an inch. In the living condition they are transparent, colourless and homogeneous. They are definite in shape, and are surrounded by a cell envelope which is a specialised part of the ectoplasm. All bacteria require for their growth a considerable amount of food material and water. There are certain types, belonging to the bacilli and spirilla groups which are motile, while others are motionless. Some are provided with flagella all round the body, in others these may be present at one or both ends. The lower forms of bacteria have no special reproductive structure, they multiply by simple fission and thus continue the species. If there is sufficient food material and conditions of temperature, oxygen, etc., are favourable, each individual organism divides into two, which again undergo similar division. Other forms of organisms are smaller and are ultra-microscopic and filter-passing. Certain bacteria, the so-called higher bacteria, come midway between the lower bacteria and the fungi and exhibit specialised reproductive structures; this suggests that they are probably closely related to the plants.

Certain bacteria which form spores have the power of protracted survival under unfavourable conditions. It is important to bear in mind that for the existence of many of the pathogenic bacteria some animal host is necessary, and except perhaps the resistant spore-bearing forms, they do not survive very long in nature apart from the bodies of animals which they invade.

All bacteria are not pathogenic and those that are pathogenic cause disturbance of health with the development of lesions which may be localised or may be disseminated throughout the body. Certain pathogenic organisms, *e.g.*, *Bact. typhosum*, *V. cholerae*, can be present in the body without manifestations of disease. Other bacteria such as *Bact. coli* are normal inhabitants of the intestine but under certain conditions become pathogenic.

The popular conception that the presence of bacteria is always associated with disease is erroneous. Human life would have been impossible were it not for the innumerable activities of bacteria which are definitely beneficial. Moreover, the bacteria found on the exposed parts of our bodies, such as *Bact. coli*, staphylococci and diphtheroid bacilli are of common occurrence. The nostrils serve as a filter for inspired air and the bacterial flora found there include varieties of cocci and bacilli; in the throat, streptococci and staphylococci are found even in the absence of any obvious signs of disease. The alimentary canal presents a highly complex bacterial flora. In a normal healthy person the stomach is comparatively sterile owing to the presence of hydrochloric acid, but the lower intestines contain an enormous variety of bacteria. *Bact. coli* and the proteus group, are present in large numbers in addition to others such as *streptococci*, *B. mesentericus* and various spore-bearing anaerobic bacilli.

The types and number of these bacteria are liable to great variations and to a great extent with the diet. The relative proportions of various organisms are variable and these organisms are compatible with a normal state of health. They are, however, potentially dangerous. *Bact. coli* in the intestine is non-pathogenic, but it may occasionally become pathogenic, as a result of imperfect nutrition, exposure to cold, interference with blood supply and some other conditions in the body of the host. In such conditions the organism invades the body and sets up pathological changes, such as, cystitis, peritonitis, etc. Streptococci in the mouth and throat may similarly cause harm and may give rise to endocarditis and arthritis. Many other bacteria which occur normally about the body may similarly be potentially pathogenic.

The bacteria which are pathogenic mostly live outside the body and then gain entrance into the body of the host. When they reach a suitable place they multiply, produce the specific disease and escape from the body and find another victim. The methods by which infection is produced are interesting. The majority of the epidemic and endemic diseases spread directly or indirectly from one individual to another. In some cases the infected person, after recovery from the illness, harbours the causative organism, in which case he is termed a 'carrier'. The carrier condition is often present during convalescence, but it is generally not of long duration, the organism being eliminated soon after the individual regains his normal health. In

the carrier condition the organism lives in harmony with the host producing no symptoms of disease, but it may still retain pathogenic properties for others. Such an individual is a constant source of danger to others.

The routes by which bacteria enter the body are various. The commonest infectious diseases, such as diphtheria, tuberculosis, etc., leave one host and enter into another by the respiratory tract. The sputum in droplets sprayed out from the mouth and nose contains infected material laden with these bacteria. Overcrowding and lack of adequate ventilation favour the infection of those whose powers of resistance are low. Another group of organisms gain entrance into the body by the mouth. Among these are the *V. cholerae*, *Bact. typhosum*, and organisms of dysentery group, which are chiefly spread by healthy carriers and by flies which feed on excreta and transfer the organisms to food. Venereal diseases, such as gonorrhoea and syphilis, are usually transmitted through direct contact between the person harbouring the organisms and the one about to be infected. Many other diseases, such as rabies in dogs, anthrax in sheep, and glanders in horses, are transmitted to man from the infected animals.

In order that a particular organism may cause an infectious disease, the association of a number of factors have to be taken into consideration. Briefly stated these are:—(1) The virulence of the specific organism, (2) the number of bacteria invading the host, (3) the channels of infection, and (4) the susceptibility and resistance on the part of the host.

Virulence of the organism. The virulence of an organism signifies its capacity to produce disease by overcoming the natural defensive mechanism of the host. The virulent bacteria have the power to multiply in the body and to produce toxic substances. Certain bacteria such as *C. diphtheriae* produce highly potent toxins but do not invade extensively, while *B. anthracis* is slightly toxic but has a greater power of invading the body. The virulence of an organism is liable to great modifications. It may be quite easily lost, for example, by growth in an artificial culture medium. On the other hand, it may be increased by passage through animals, that is, by transfer from one animal to another. The explanation of such heightening in virulence is that the virulent ones grow rapidly and readily in the animal tissue while the avirulent organisms tend to disappear with the result that the surviving strain contains a greater proportion of virulent bacteria.

The number of bacteria. To produce an infection it is necessary that a requisite number of bacteria invades the tissue. It has been shown experimentally that a single anthrax bacillus may cause fatal infection in about 28 per cent. of mice, while 10 anthrax bacilli are capable of destroying all the mice infected. Infection is most likely to develop when the invading organisms reach the host in large

numbers and frequently, and it is for this reason that epidemics of respiratory diseases, such as influenza, originate in thickly populated places.

Channel of infection. The route of entrance of the infective organism and the vector by which it is conveyed to the host are very important from the point of view of prophylaxis and treatment of diseases. Certain organisms, *e.g.*, *Bact. typhosum*, and the dysentery group of organisms enter by the mouth and the characteristic lesions due to those organisms are found in the intestinal canal. Thus it has been shown that direct inoculation of these organisms into the tissues is incapable of causing the disease. Other organisms such as the *C. diphtheriae*, *Fusiform fusiformis*, usually select the mucous membrane of the fauces and larynx as their primary sites of attack.

Susceptibility of the host exerts a marked influence on the course of the infection. So long as the chemical substances produced by the metabolism of the parasite are innocuous or helpful to the host, there will be no reaction against the invading organism. But certain organisms produce chemical substances such as toxins which damage the tissues of the host. In such cases, some reaction on the part of the host is bound to develop. It is probably rare for the bacteria to be present initially in such numbers or to possess so high a degree of virulence as to paralyse completely the natural defensive mechanisms of the host. Thus there is always a struggle going on between the natural defensive mechanism of the body and the invading organism; the more prompt and efficient the response of the host, the better is the outlook. There is good ground for belief that any agency which interferes with the general health of the patient or which damages the tissues of the host will diminish natural or acquired resistance to infection. Thus fatigue and chronic alcoholism cause a general deterioration of health; injudicious diet predisposes to disturbances of the alimentary canal and increases the susceptibility to bacterial infection; trauma mechanically opens a road into the tissues and creates a nidus for the growth and multiplication of the invading organisms.

CHEMOTHERAPY OF BACTERIAL DISEASES

Chemotherapy of infections with common bacteria such as streptococci, staphylococci, pneumococci, tubercle bacilli, etc., has been developed along two lines, (a) the employment of antiseptic substances whose antibacterial properties are relatively high as compared with their toxicity for animal tissues, and (b) the metal-salt therapy, the substances being used in doses which have probably no direct action on the organisms.

For a substance to be successful in killing bacteria in the circulating blood, two essential conditions must be fulfilled. It should, after injection, attain a concentration in the blood lethal to the microbes but at the same time be harmless to the host, and it must maintain such a concentration sufficiently long for the microbes to be killed.

If a germicide is introduced into the circulation, the concentration of the drug will be at its maximum immediately after the injection, and simultaneously with it, the bactericidal power will also be at its highest. If, on the other hand, there is no increased bactericidal power of the blood immediately after the injection, but only after a lapse of time, such an increase cannot be ascribed to the drug alone, but to some other factor. This is significant from the fact that normal human blood has got a great bactericidal property. It has been found that 1 c.cm. of human blood when incubated with 2,000 to 5,000 staphylococci can destroy 90 per cent. of the cocci. When chemotherapeutic substances are injected into the blood, the reaction that takes place is complex. These agents may act directly on the organisms so as to cause their death, or, their action may be an indirect one due to stimulation of the natural defensive powers of the tissues. Both these factors may come into play. If the vitality of the organism is lowered by direct action, then the cellular and humoral tissue defences may be enabled to come into play. Further the products resulting from the destruction of the organisms act as antigens, and in this way immunity reactions are developed.

While the treatment of protozoal and helminthic infections with chemicals has attained a considerable measure of success, the treatment of bacterial diseases, on the other hand, is still unsatisfactory. Most of the chemical bactericidal substances at present in use precipitate proteins and are therefore general protoplasmic poisons. They, therefore, destroy the resisting power of the tissues to infection. Moreover, they are rapidly removed from the circulation after an intravenous injection and hence the effect produced is of a temporary nature. In the case of wounds, the treatment with chemicals presents a complicated phenomenon. Experimental evidence that an antiseptic can

afford benefit by directly killing the organisms with which it comes into contact has been advanced, but it has not yet been accepted generally. The strength of such an antiseptic will rapidly fall below the concentration in which it has any bactericidal effect. On the other hand the harmful effects produced by the drug on the tissues, such as necrosis and damage to the leucocytes, outweigh its other action, so that the surviving bacteria are thereby able to propagate the infection more freely. Thus most of the antiseptic substances that are known, such as eusol, Dakin's solution and the antiseptic coal tar derivatives, lose much of their potency in a very short time.

Antiseptics have been tried in generalised and remote bacterial infections in the same way as therapeutic agents are now employed to destroy protozoa. It has been shown experimentally in animals that, after intravenous injection of various dye-stuffs, the blood becomes rapidly bactericidal and this property is retained for some time afterwards.

Koch first carried out a series of experiments with a number of drugs to produce disinfection within the body in cases of septicæmia. He tried mercury compounds, but these proved useless because they were inactivated by the proteins of the blood. Innumerable drugs have since been tried in bacterial diseases but the success has been very limited. Experiments *in vitro* do not always represent the results that may be obtained *in vivo*. Drugs having highly bactericidal properties *in vitro* do not necessarily ensure chemotherapeutic activity *in vivo*. Moreover the action of a drug in combating a bacterial infection of the tissues in animals cannot be applied *in toto* in clinical trials in man.

In this connection another important point has also to be considered. Different species of bacteria possess different powers of resistance to various drugs. Compounds of chlorine, phenol and mercury show considerable differences in their power to kill different bacteria, and their specificity can be greatly augmented or retarded by changes in their structure. For example, the halogen compounds of naphthol have been found to possess high bactericidal activity against *C. diphtheriæ* and *Bact. coli*. The coal-tar dyes also show marked specific

action and many of them have been utilised in infection with bacteria of the typhoid-paratyphoid-dysentery groups.

The specific disinfecting property of drugs is nevertheless of great importance from the standpoint of investigation into the chemotherapy of bacterial diseases. In addition there is the possibility of finding some substance which may possess sufficiently strong selective action in certain diseases of bacterial origin so that they may be useful in the internal disinfection of the tissues.

The following substances among others have been used in bacterial infection and will be described in some detail.

- (1) Aniline dye compounds. (2) Hydrocupreine derivatives.
- (3) Phenols and their derivatives. (4) Metallic and other compounds.
- (5) Chaulmoogra oil and its derivatives (see chapter on leprosy).

Phenyl methane dyes. The basic dyes of this group such as gentian violet, crystal and methyl violet have a selective lethal action on Gram-positive bacteria and much less for the Gram-negative organisms. They have a low toxicity for tissues and penetrate them readily. They have been tried in cases of staphylococcus infection both locally and intravenously.

Gentian violet is said to be harmless to the tissues and is bactericidal especially against staphylococcal infection. A local application in strength of 1 in 10,000 to 1 in 500 has been found useful. Young and Hill (1924) obtained good results with intravenous injection of the drug in septicæmia, chronic cystitis, etc. It is, however, a slowly acting germicide and leaves the blood stream very rapidly so that a minute or two after the injection the blood is no longer bactericidal. It would, therefore, be impossible to maintain in the circulation a bactericidal concentration for sufficient time to kill the microbes. Brilliant green another of these compounds, has been shown to possess high bactericidal property. Browning (1918) found this substance to be lethal to *Staphylococcus aureus* in dilution of 1 in 10,000,000 but the action is reduced in the presence of organic matter. Kligler (1910) showed that brilliant green killed *B. subtilis* and *Staphylococcus aureus* in dilutions of 1 in 15,000,000 and 1 in 4,000,000 respectively, while a concentration of 1 in 600,000 was necessary to kill *Bact. coli*; the dysentery group of organisms was killed in dilution of 1 in 1,500,000. Acid and basic fuchsin have also been tried and are said to possess high bactericidal power.

Acridine dyes. Acridine was introduced by Ehrlich in 1912 as a trypanocide under the name of trypanflavine; it is now known as acriflavine. Many acridine dyes have since been studied but only acriflavine and proflavine are actively antiseptic even in the presence of

wound-secretions. Although in many cases beneficial results have been obtained, there are many instances in which these dyes have proved ineffective. Acriflavine has been tried, like other dyes in influenzal pneumonia, urethritis, pyelitis, etc., but the results have not been encouraging.

Investigations have also been carried out on the bactericidal property of certain alkoxy derivatives of diamino-acridines. The most widely used of these compounds is rivanol which has been tried in the treatment of amoebic dysentery. The results of experiments with many of these compounds on streptococci *in vitro* are given below (Pindlay) :—

Compound.	Highest bactericidal dilution.
2-methoxy-9-ethanolamino acridine	... 1 in 60,000
2-ethoxy-9-ethanolamino acridine	... 1 in 80,000
2-allyloxy-9-ethanolamino acridine	... 1 in 100,000
2-propyloxy-9-ethanolamino acridine	... 1 in 40,000
2-isobutyloxy-9-ethanolamino acridine	... 1 in 40,000
2-isoamyloxy-9-ethanolamino acridine	... 1 in 16,000

Although many of these dye-stuffs have been shown to possess high bactericidal activity they have not been found effective in the treatment of diseases. Some of them produce toxic symptoms when given internally, while others are rendered inert in the body by combination with the proteins of the blood.

Hydrocupreine derivatives. The alkyl derivatives of hydrocupreine have been found to possess high bactericidal efficiency. The germicidal property of these compounds varies for different types of bacteria. Ethyl hydrocupreine is lethal to pneumococci while the higher derivatives such as eucupreine and vuzine are toxic to pus-forming organisms.

Experiments with optochin have shown that it is beneficial in pneumococcal infections. *In vitro* the drug inhibits the growth of pneumococci in concentration of 1 in 800,000 in serum; it kills them in 1 in 400,000 solution. The clinical efficiency in pneumonia in man however has been far less encouraging. Some clinicians have reported improvement if the drug is given in the first two or three days of the disease. Its application is limited by the fact that therapeutic doses are liable to produce toxic amblyopia.

Various other cinchona derivatives have also been tested for their bactericidal effect, and some of these compounds possess high bactericidal action *in vitro* but their action *in vivo* is feeble.

Phenol and its derivatives. Phenol is a general protoplasmic poison and a fairly active disinfectant. It precipitates proteins, but

the combination is so loose that it is split up allowing the compound to penetrate deeply into the tissue or into the body of the micro-organism. The bactericidal action of phenol depends upon its solubility in lipoids and proteins. Any condition which diminishes its solubility greatly interferes with the antiseptic property, hence alcohol or alkalies inactivate the effect of phenol. It has been shown that phenol kills *Bact. typhosum* in a few seconds at a concentration of 14 parts per 1,000, but dilution diminishes its bactericidal effect. Tubercle bacilli are killed by exposure to 5 per cent. solution for twenty-four hours.

By the introduction of an alkyl group into phenol, a series of compounds are produced which have great germicidal power. The most important of these derivatives are the cresols. The three isomers ortho-, para-, and meta-cresol differ in their bactericidal property, the meta- possessing the highest germicidal power being at the same time the least toxic; para- is the most toxic of all.

It has been found that among the various cresols, lysol, cyllin, izal, etc., have rapid bactericidal action in strong concentration, but they lose their activity in dilution. Chick and Martin (1908) showed that disinfectants of this class were ten times more bactericidal than phenol but quickly lost their activity in the presence of organic matter. The germicidal activity of these compounds is measured by determining the phenol co-efficient, that is, the ratio of the germicidal power of the disinfectant to the germicidal power of phenol, both being tested under identical conditions.

Caius and others (1927) studied the bactericidal action on *Past. pestis* of some commoner phenols and their derivatives *in vitro*. They found that introduction of the hydroxyl group into the benzene nucleus with the formation of phenol, greatly increases the antiseptic properties. The introduction of alkyl groups into the nucleus further augments the bactericidal power as shown by the three isomeric cresols which are better antiseptics than phenol. Solution in alkali either depresses or intensifies the effect of monohydric alcohols; the bactericidal power of thymol is depressed while that of carvacrol is intensified. In the case of the polyhydric alcohols, the bactericidal power is intensified in alkaline solution.

Etherification lowers the antiseptic value of dihydric phenols and the entrance of a propenyl radical, whether allyl (eugenol) or isoallyl (isoeugenol) in the molecule of guaiacol, enhances the bactericidal power. Among the substituted phenols the entrance of chlorine or bromine into the nucleus of phenol causes an increase in bactericidal power, as 2: 4: 6-trichlorophenol is sixteen times more powerful than phenol. The entrance of an amino group increases the bactericidal power.

In the case of the phenol derivatives, the nitroso derivatives act more slowly than resorcinol, the mononitro derivative is three times as active as resorcinol, while di- and tri-nitro derivatives are less powerful;

the entrance of the amino radicle increases the bactericidal power. The entrance of the nitroso radicle into the molecule of beta-naphthol increases the bactericidal power to sixteen times. Alkylation, halogenation and esterification augment the bactericidal power of phenolphthalein. Nitration increases the bactericidal power of fluorescein and its derivatives.

Though many of the phenol derivatives are good germicides and have been used for disinfection purposes and as antiseptic lotions for wounds and ulcers, internal disinfection with them has been a failure. Moreover they are markedly toxic when given internally.

Metals and their compounds. All heavy metals in high dilutions inhibit the growth of bacteria. It has been shown that 1 in 100,000,000 of copper in distilled water kills algæ. The colloidal metals in which the metallic particles are in an extremely fine state of division are physiologically inert; the only action which they can produce is by a small number of ions and this is inappreciable. Their therapeutic value in the treatment of bacterial diseases is very doubtful.

Most of the metallic salts have bactericidal properties in very high dilutions, dilutions such as would occur in the body after their administration in therapeutic doses. Copper sulphate kills *Bact. typhosum* in two hours in dilutions of one in a million in distilled water; mercuric chloride destroys the same organism in the same dilution in 24 hours. Many other metallic salts act in the same way. Unfortunately this action is very greatly weakened in the presence of electrolytes, and organic matter still further reduces this action. Their value in destroying bacteria in the tissues is therefore very doubtful.

It may be mentioned here, however, that although heavy metals cannot destroy bacteria in high dilutions in the presence of electrolytes and organic matter, they inhibit the growth of bacteria in very high dilutions. For instance it has been shown that mercuric chloride inhibits the growth of bacteria in nutrient broth culture media in a dilution of one in a million due to the liberation of metallic ions. This is the only kind of action which may be expected to take place in the body after administration of these compounds, and it may not be of much value in the actual treatment of many bacterial diseases where rapidity of action is imperative. The utility of most of these compounds is at present almost entirely confined to external disinfection and antisepsis of the skin, mucous surfaces, wounds, etc.

A few organic compounds of mercury and arsenic have been used in bacterial infections.

Mercurochrome, an organic mercury compound, has been much used as a germicide for intravenous injection. It has been recommended in many microbic infections, the chief of which are staphylococcus, and *Bact. coli*, the quantity used being about 0.005 gm. per kilo. body weight which gives a concentration of about 1 in 15,000 in the circulation. Fleming (1931), however, showed that in de-leucocyted blood mercurio-

chrome in a concentration of 1 in 2,000 has no power of inhibiting the growth of staphylococci while with normal blood the drug has no antibacterial power itself, but on the contrary impairs the natural bactericidal power of blood.

Mercurochrome has no germicidal action in a concentration more than twice the maximum obtainable after an intravenous injection. For further information see the chapter on mercury in Part III.

Walburn (1921) found that animals could be protected against lethal doses of organisms or toxins in many cases by a series of intravenous or subcutaneous injections of salts of certain metals. This he attributed to a temporary increase in the antibody content of the blood. Though general confirmation of his results is lacking, certain striking facts have been established with regard to the chemotherapy of metal-salts in infections with bacteria. It has been found that the action of these metals depends on (1) the pathogenic agent and on the species of the host, *i.e.*, the same metals are not effective against all the pathogenic agents, and also the same metals do not act similarly in animals of different species, (2) dosage: there being an optimum range of dosage an increase beyond which fails to influence the various infections and intoxications, and even may accelerate death, although the amounts which lead to these harmful effects may not in themselves be toxic for the host; (3) the time of commencement of treatment; (4) the virulence of the infecting organism, since in certain circumstances an infection with highly virulent organisms may be more amenable to treatment than one with the same organism but of lower virulence; (5) the diet of the treated animals.

In addition it has also been shown that metal-salts, which are therapeutically inactive alone, may be effective when administered along with homologous vaccine or antiserum. Thus Walburn showed that neither the injection of manganese-salt by itself nor of a vaccine of killed 'rat' bacilli alone cured mice infected with these organisms, but a combination of the two was effective.

Organic arsenic preparations. The efficacy of organic arsenical preparations in spirochaetal diseases is recognised. Douglas and Colebrook (1916) showed that salvarsan had a considerable bactericidal power on the hæmolytic streptococcus. Allison (1928) used it successfully in puerperal sepsis. Colebrook (1928) found the organic arsenicals to be specific against hæmolytic streptococci. He showed that with novarsenobillon a sufficient concentration in the blood can be reached which is lethal to the hæmolytic streptococci.

The organic arsenicals can therefore act as germicides in the circulating blood and they are useful in this respect in streptococcal infection and in anthrax infections. See also section on arsenic and treatment of individual bacterial diseases.

Other bactericidal substances. The bactericidal properties of the halogens and their derivatives are well known. A number of compounds

of chlorine are commonly used for disinfection of body tissues, *e.g.*, *eusol*, Dakin's solution, chloramine-T, dichloramine-T, etc. The action of these compounds is due to chlorine which occurs in them in a state of loose combination so that it is rapidly given up in the presence of proteins. The chlorine thus liberated combines with all forms of other proteins, including those of bacteria and in this way kills them. The disadvantage of these compounds is that when excess of other proteins is present, the chlorine combines with them and ceases to act as a bactericide. Chloramine compounds are more stable and give up their chlorine more slowly than compounds like *eusol*. They have therefore better disinfectant and antiseptic properties in contact with the body tissues. Compounds of iodine act in very much the same way.

Hydrogen peroxide and potassium permanganate owe their action to liberation of nascent oxygen. They readily decompose when brought in contact with the body tissues. Formaldehyde has a powerful destructive action on bacteria but is equally destructive to the tissues.

Conclusion. A perusal of what has been said above will show that, although we have many compounds which have a marked destructive action on bacteria and which are even effective in the treatment of external lesions produced by bacteria, the problem of obtaining substances which will produce internal disinfection and antisepsis still remains to be solved. Further research with such substances as aniline dyes, which have more marked bacteriotropic and less organotropic properties, is being carried out. It is hoped that compounds may be discovered in the near future which will destroy bacteria in the body tissues in the same way as therapeutic agents now destroy protozoa in the tissues. Till such compounds are discovered the specific treatment of bacterial diseases must be mainly with vaccines and sera, which only play a secondary part.

CHAPTER II

SPECIFIC IMMUNE THERAPY IN BACTERIAL AND VIRUS DISEASES

In the prophylaxis and treatment of a large number of bacterial and virus diseases specific immune therapy has been extensively employed. This therapy consists of two measures, one having for its object the specific stimulation of the natural immunity mechanism of the body through the inoculation of a suitable suspension of the causative agent of the disease, *vaccine therapy*, and the other aiming at the destruction of the infecting organism or the neutralisation of its toxins, through the inoculation of ready-made specific substances or antibodies which are present in the sera of immunised animals, *serum therapy*. These two measures are suited for different types of diseases and when appropriately used they produce favourable therapeutic results. Serum therapy has been found invaluable in certain acute infections, where a rapid neutralisation of the poison is indicated and where it is desired to aid the overtaxed immunity mechanism of the patient. Vaccine therapy on the other hand has been of great benefit in prophylaxis and in treatment of a number of chronic localised infections, where the patient is not too ill and his immunity mechanism is not exhausted. But unfortunately at the present time, because of the growing tendency to apply these remedies in all sorts of unsuitable conditions, both forms of specific immune therapy in general and vaccine therapy in particular, have fallen into disrepute. In many instances the practitioner employs vaccine therapy not because he considers it suitable but because other remedies have failed and he cannot think of anything better. The common excuse is that "if vaccines do no good, at least they do no harm." This appears illogical, as we believe that any remedy that has potentialities for doing good also possesses the power to do harm, if improperly used. The unscientific attitude, the commercial exploitation of vaccine therapy, and

the utter disregard of the results which observation and experiment have made available, are to be greatly deprecated. The improper application of the therapy will only retard the progress of science and will help neither patient nor practitioner. It is the clear duty of the medical practitioner, by study and knowledge of the latest advances in immunology and bacteriology, and through the proper and scientific application of these valuable therapeutic agents, to contribute towards the progress of science and thus to the ultimate well-being of the community.

VACCINE THERAPY

The word vaccine is from the latin *vacca*, a cow. Cow-pox was called *vaccinia* or cow-disease and Jenner designated protective inoculation against small-pox with cow-pox virus as *vaccination*. Pasteur adhered to Jenner's nomenclature and applied the term *vaccine* to the suspensions of attenuated and killed bacteria that he used for immunisation. At present the term *vaccine* may be defined as a killed and enumerated suspension of organisms or their products, which when inoculated into the body, stimulates the tissues to produce antibodies which directly or indirectly bring about the destruction of the invading organisms and the neutralisation of the poison that the organisms may have produced.

Vaccine therapy has been in practice for a considerable length of time. In ancient China and India, the people had observed that one attack of small-pox protected them from subsequent attacks. They put this observation to practical use by exposing their children to mild cases of small-pox in order that a mild infection might be acquired and a lasting immunity secured. This practice was, of course, crude and attended by grave risks as it sometimes resulted in virulent infection and death. Many centuries later, Edward Jenner, as a result of his own observations and experiments, proved that cow-pox virus when inoculated into human beings produced a trivial infection followed by an absolute immunity against small-pox. Although he could not explain the principle or mechanism involved in

the process of immunisation, he may be justly considered to have laid the foundations of prophylactic vaccination. After Jenner, came Pasteur who while working with the organism of chicken cholera found that by leaving virulent cultures of the organism at the laboratory temperature for some weeks they became innocuous to chickens and were capable, when inoculated, of producing immunity in them. These inoculated fowls proved resistant to a subsequent inoculation with virulent organisms. From this he conceived the idea that by attenuating virulent organisms, and inoculating them into animals immunity might be produced. He put his theory into practice in a number of other bacterial infections and obtained convincing results. He established the value of prophylactic vaccination beyond any doubt. Following upon Pasteur's discoveries, preventive inoculation began to be widely practised both in animals and in man. In all his vaccines, Pasteur used attenuated living virus. The use of such vaccine in human subjects was attended with a certain amount of risk.

Salmon and Smith (1884-86) were the first to show that injection of dead cultures of bacteria were capable of establishing immunity in animals. But it was not till the work of Haffkine, Pfeiffer, Kolle and Wright, several years later, that the modern method of prophylactic vaccination in man was well established. Wright and his colleagues advocated its use for curative purposes, and according to them the justification for curative vaccination lay in the fact 'that in many instances infections are localised and that, while the local capacities of resistance may have been lowered, the immunity mechanism in other parts of the body may not have been brought into play and that vaccines by stimulating these may flood the focus of infection with antibodies and phagocytes and overpower the causative agent.' The experience gained during the past fifty years has vindicated in a convincing manner the value of vaccine therapy both in the prophylaxis and cure of disease.

A considerable amount of controversy has taken place as to the comparative value of living attenuated vaccine and vaccines prepared from killed cultures. Considering that a

certain amount of risk is attended with the use of living organisms for this purpose, the general opinion is in favour of the use of vaccines prepared from killed cultures.

Preparation of vaccines. Since the inception of vaccine therapy various methods have been devised for the preparation of vaccines. The selection of strains for such a purpose is very important according to our recent knowledge on bacterial variation. It has been shown by Arkwright (1927) in regard to *Bact. typhosum*, that in cultures there appeared colonies which had a 'rough' appearance while the normal colony was 'smooth' and shiny. These terms are now expressed by the letters 'R' and 'S,' the 'S' type is usually the normal pathogenic form, 'R' being the degenerate avirulent modification. 'R' variants are useless as protective vaccines. In view of this it is essential that in the preparation of vaccines 'R' variants should be rigidly excluded.

In addition to this, another type of variation, which is known as 'H' and 'O' variations of the organisms, has great significance from the point of view of immunity production. Smith and Reagh (1903) demonstrated the difference in the agglutination reactions between motile and non-motile forms of the same organism and later Weil and Felix (1916) working on the agglutination of *Proteus vulgaris*, differentiated two types of colonies in the culture ; the one is of a spreading type and the other discrete. The former is known as 'H' variant and the latter 'O' variant. It has been shown that the 'O' antigen of the smooth type of organisms is the one which is most important in the production of immunity and the 'H' antigen and the 'R' somatic antigen are of no protective value. In addition to these there is some other immunogenic antigen which is heat labile and it has been shown by Iyengar that over-heated vaccines of *Past. avisepticus* are inferior to vaccines heated to 60°C. or less.

The vaccines in common use are prepared in one of the three ways, depending upon the nature of the organism concerned; the ideal aimed at in the preparation is to render the organisms innocuous and to modify its antigenic structure as little as possible.

1. The ordinary vaccine is a suspension of killed organisms in normal salt solution. The organism is first isolated in a pure state by using a suitable culture medium. To an 18 to 24 hour culture of the organism normal saline is added and a uniform suspension of the organism obtained. The organism in the suspension is then killed without altering its antigenic structure by minimum heat or by addition of antiseptic, such as phenol. The purity and sterility of the vaccine are tested and the number of organisms per c.cm. enumerated. Finally the suspension is brought down to the required strength by dilution with 0.5 per cent. carbolic saline.

2. In diseases like small-pox and rabies the causative agent (filtrable virus) cannot be grown in artificial culture media. Therefore to prepare vaccines of these viruses they are cultivated in the tissues of animals (on the shaved skin of the abdomen of healthy calves in the case of small-pox virus and in the brain of sheep in the case of rabies virus) and an emulsion of the infected tissues made and tested for purity bacteriologically. The preparation and standardisation of these vaccines require great care and technical skill and in some countries a license has to be obtained for preparing these and only well equipped laboratories of a first class nature are granted permission to manufacture them.

3. For the preparation of vaccines which consist of the exotoxin or endotoxin of organisms, as for example, Koch's tuberculin, diphtheria, tetanus and scarlet fever toxins, the organisms are grown in special fluid media and when the maximum degree of toxicity is reached the medium is filtered, the bacterium-free filtrate standardised and vaccine prepared from it.

Varieties of vaccines. 'Live' vaccines. As the name implies the organisms in this vaccine are alive and not dead. Theoretically the ideal form of vaccine is the 'live' vaccine, because there is experimental proof that it calls forth a maximum response of antibody. In the prevention of small-pox the marvellous results obtained are due partly to the fact that the vaccine used is a 'live' vaccine. Recently, Alcock has used 'live' vaccine in gonorrhoea, but his results are not encouraging. While there are advantages in using a 'live' vaccine, the procedure is attended with grave risks and, therefore, cannot be recommended as safe for employment in human cases, except in a few select instances.

Sensitised vaccines. These were originally introduced by Besredka, and are prepared by growing the organism in suitable media and then mixing it with the appropriate immune serum, allowing the specific antibodies to get absorbed on to the organism, centrifugalising the suspension and finally resuspending the sensitised organism in normal saline. The vaccine is really a sero-vaccine and has antibodies present in it along with the organism. By sensitising the organism, the therapeutic value of the vaccine is said to be enhanced because larger doses can be given and there is very little reaction after injection. The preparation of sensitised vaccine is not only difficult and expensive but it is also not possible for all organisms. It can be made only in those cases where a potent specific anti-serum is available. It is commonly used in streptococcal infections and is well tolerated even by patients suffering from acute and generalised infections.

Autogenous vaccines. These are vaccines prepared from the organism causing the infection in the patient. Here one is certain that the vaccine prepared is antigenically specific and will give rise to antibodies that will produce maximum good to the patient. Wherever possible autogenous vaccine made by a competent bacteriologist should be used.

The recent advances in our knowledge on the antigenic structure of organisms and their powers of variation fully justify this view. When laboratory facilities are available as in big cities there is no excuse whatsoever for not getting an autogenous vaccine made. The indiscriminate use of stock vaccine has contributed largely to the disrepute into which vaccine therapy has fallen in certain quarters. In cases such as gonococcal arthritis where the infecting organism is difficult to isolate by cultural methods the use of stock vaccines is justifiable.

Stock vaccine. This term is applied to vaccines prepared from cultures of organisms obtained not from the patient but from others who have previously suffered from similar infections. This vaccine is readily available at a cheap cost to the practitioner. The vaccines put up in the market by commercial firms are of this nature. The chief objection to their use is that one cannot be certain in every case that the organism in the vaccine is antigenically the same as the organism in the patient. In the case of organisms like *Bact. typhosum* and staphylococcus in which different strains exhibit serological homogeneity there may not be much difference between stock and autogenous vaccines, but in the case of streptococci, pneumococci, *Bact. coli* and *H. influenzae* it is best to avoid stock vaccines as far as possible. All prophylactic vaccines are, however, stock vaccines prepared from a large number of strains.

Polyvalent vaccine. This is a vaccine consisting of several strains of the same organism isolated from different cases. In the case of organisms like streptococci and *Bact. coli* in which several serological "strains" are known to exist, polyvalent vaccines should always be used. Even when autovaccines are prepared of these organisms, a number of colonies of the organism in the culture should be selected for use. For prophylactic purposes polyvalent vaccines prepared by reputed laboratories should alone be used.

Mixed vaccine. This term is applied to vaccines composed of two or more organisms. When mixed vaccines are inoculated antibodies are produced against the different antigens present. These vaccines are generally employed in chronic infections of the respiratory tract, in which one generally gets a number of different bacteria in culture and is not certain which one of these is causing the disease and is important from the point of view of vaccine therapy. While it may be advisable to incorporate into a vaccine all the pathogenic organisms isolated from a case, experience shows that it is best not to use too many species.

Detoxicated vaccine. In the preparation of this vaccine, an attempt is made to remove the endotoxin contained in bacteria, so that larger doses of the vaccine may be used without giving rise to severe reactions. This may be done by dissolving the organisms in alkali and then precipitating by acids. How far it is possible to separate the endotoxin from an organism without altering the nature of the antigen contained

in it cannot yet be ascertained. One is also not certain if the endotoxins are after all unnecessary ; they certainly stimulate antibody production and as such may be helpful in immunity. The only advantage in using detoxicated vaccines seems to be that large doses can be given without producing undesirable reactions, but this advantage will be negligible unless there is an assurance that the usefulness of the vaccine is not reduced.

Formolized vaccines have been used in cases where the culture of the organism produces a powerful toxin. It has been shown that toxins treated with formalin lose the toxic property but retain the antigenic property. This principle has been applied to whole cultures. Broth cultures or saline suspensions of organisms are incubated with 0.2 to 0.5 per cent. formalin which procedure kills the bacteria, and where exotoxin exists, converts it into a nonpoisonous toxoid but still retaining its antigenic properties. It has been used with great success in the case of Shiga's dysentery bacillus (Ramon and Dumas, 1925, Durmand, 1925).

Defatted vaccines. Douglas and Fleming (1921) claimed that a tryptic digest of acetone-extracted bacteria furnished a good antigen. Dreyer (1924) prepared tubercle vaccine by first boiling the organisms in formalin and then extracting them with acetone. He claimed to have cured tuberculosis in guinea-pigs with the use of such a vaccine. Clinical trial in man appeared to be favourable in the beginning, but later observation did not show any advantage of this type of vaccine over the ordinary vaccines.

Lipo-vaccines. In these the bacteria are suspended in an oily medium, so that the vaccine substance would be slowly absorbed and the antibody-producing stimulus would be prolonged, thus approaching more nearly the condition in an actual infection. The available evidence goes to show that these are less effective than the ordinary vaccine suspended in saline solution.

Vaccines killed by chemical substances. Vaccines killed with various chemicals such as ether, iodine, and sodium fluoride have been extensively used in France with the idea that these not only kill the vegetative forms of bacteria but also detoxicate them, but they have not found favour anywhere else.

Bacterial extracts, filtrates and digests. With the idea that antigen in solution can react immediately with the body cells thus enhancing the immunisation process such extracts have been used. Although these are antigenic there is as yet no evidence to show that they are superior or even equal to the simple bacterial vaccine.

Autolysates. Sometimes the breaking down process proceeds too far and the immunising power of the vaccine is lost. More work is needed in this direction before this type of vaccine can be advocated for general use. In this connection it may be stated that bacteriophage is really a combination of bacteriophage and vaccine.

Antiviruses. These were introduced by Besredka (1919-24) with the idea that filtrates of cultures which have stopped growing contain inhibitory substances to which he gave the name 'antivirus.' He claims that animals inoculated subcutaneously or intradermally or poulticed on their shaved skin with staphylococcal or streptococcal antiviruses are resistant to inoculation of virulent cultures introduced 24 to 48 hours later. But this has not been substantiated by other workers.

Standardization of bacterial vaccines. In India at the present time no control whatsoever is exercised over the production and sale of therapeutic substances. Vaccines are therefore being largely used by practitioners without any knowledge of their nature or efficacy. The relevant clauses from the regulations issued under the Therapeutic Substances Act are outlined below :—

"The proper name of any vaccine shall be the name of the micro-organism from which it is made, followed by the word 'vaccine' unless the relative Schedule otherwise provides or if there is no provision in the relative Schedule some other name is approved by the licensing authority, provided that in the case of the under-mentioned preparations the proper name of the vaccine may be as follows : *Anti-typhoid vaccine; anti-typhoid-paratyphoid vaccine (T.A.B.); anti-typhoid-paratyphoid-cholera vaccine (T.A.B.C.); anti-plague vaccine; anti-dysentery vaccine; whooping-cough vaccine.* Cultures used in the preparation of vaccines must, before being manipulated into a vaccine, be thoroughly tested for identity by the generally accepted tests applicable to the particular micro-organism. The permanent record, which the licensee is required to keep shall include a record of the origin, properties and characteristics of the cultures."

"Vaccines may be issued either singly or combined in any proportion in the same container. In the case of combinations of vaccines a name for the combined vaccine may be submitted by the licensee to the licensing authority, and if approved may be used as the proper name of the vaccine."

"The label on the container shall indicate the composition of the vaccine by reference either : (a) to the number of micro-organisms per c.cm.; or (b) to the weight of dried substance of micro-organisms per c.cm.; or (c) to the number of micro-organisms or weight of dried substance of micro-organisms used in preparing 1 c.cm. of the finished product."

Methods of administration. Vaccines are administered by the following routes :—

Subcutaneous. This is the route commonly chosen. Vaccines are best given at a point where the tissues are loose. The popular site is the outer aspect of the arm about one-third of the distance down from the shoulder to the elbow. When large quantities have to be given as in antirabic treatment the sides of the abdomen may be preferable. In the case of localised lesions some believe that injection of the

vaccine near the lesion is more advantageous, but there is no evidence in support of it.

Intravenous. Vaccines are sometimes given intravenously for the purpose of eliciting marked reactions. In the treatment of arthritis, typhoid, coli and gonococcal vaccines have been given in this way. The beneficial results noticed appear to be due to the non-specific protein reaction that follows rather than to the route of administration.

Oral. There is experimental evidence to show that oral administration of killed cultures of bacteria and certain toxins and poisons, to mice and rabbits, results in the production of a certain degree of immunity. Vaccines have, therefore, been given by the oral route specially in little children and in patients who cannot overcome their antipathy to inoculations. Besredka's bih-vaccines are prepared specially for oral administration. From the available evidence it is certain that the oral method is not preferable to the subcutaneous method; it is even doubtful if it is efficacious at all.

Intracutaneous. Small-pox vaccine is used in this way. The cleaned skin is scratched gently by a needle or lancet, care being taken not to draw blood and then the vaccine lymph is applied to the scarified part and allowed to dry. Some prefer to give bacterial vaccines also by this route, but the advantages claimed are of doubtful value.

Dosage. Dosage varies not only with the nature of the vaccine used but also with factors such as age of the patient, nature of the illness, toxicity of the organisms, sensitiveness of the tissue affected, route of administration and the purpose of administration. In young children, in acute illness, when sensitive tissue like the lungs or the brain are involved, when the selected route of administration is intravenous or the purpose for which it is used is for cure of illness, the dosage has necessarily to be small. On the other hand, in adults, in chronic illness of a localised character, when the route is subcutaneous or when the purpose is prophylaxis, a larger dose will not be harmful. The first dose is purely an experimental dose, and the subsequent doses must be controlled by the local, focal and general symptoms. The production of any marked reaction, either local or constitutional, after an injection may be considered a contraindication to any increase in dosage. The time interval is another important factor to be considered. As a rule, 3 to 5 days or 7 days' intervals between doses is given for chronic or subacute infections and 48 to 72 hours' intervals in acute cases, but there is no hard and fast rule and the reaction

of the patient is the best guide. When stock vaccines are used the dose may be two or three times as large as those of auto-genous vaccine and when used for prophylactic purposes they may be about five times the initial dose. For assessing the importance and value of the different factors discussed, experience alone is the chief guide.

Reaction following administration. Local, focal and general reactions may be noticed after vaccine administration. In prophylactic inoculation where a large dose of vaccine is given, local and general reactions are common. The first is characterised by pain, swelling, redness and heat at the site of inoculation, and the second by slight chill, rise of temperature to 100 or 101°F., nausea, and headache. These symptoms usually subside within 24 hours. In curative inoculation on the other hand neither of these two reactions is generally present specially if the dosage is carefully chosen. It is advisable, in the best interest of the patient, to avoid these constitutional disturbances. The initial dose being a trial one, there may occur some slight focal reaction, but this should not be allowed to recur. Focal reaction is of a mild nature and disappears spontaneously.

Therapeutic Uses

The most convincing results have been obtained by the use of vaccine for prophylactic purposes. There is little doubt about the efficacy of the preventive inoculation in small-pox, rabies, typhoid fever, and plague. As regards diseases such as diphtheria, scarlet fever, cholera, influenza and pneumonia, the results are encouraging. On the other hand the therapeutic use of vaccines has not been very successful so far, but lately they have been used more extensively with greater success on account of the better method of preparation due to the recent knowledge on immunity reactions in relation to the antigenic structure of organisms. The success depends not only on the proper preparation of vaccines but also on the proper choice of cases. Experience alone can overcome these difficulties, and for this reason it is best to consult a competent bacteriologist who can advise as regards the suitability of the case as well as about the preparation and administration of the vaccine. When

a course of an autogenous vaccine fails to produce the desired effect, attempts should be made to detect any fresh infection by some other organism or by a different serological type of the same organism. In either case a fresh autogenous vaccine should be prepared incorporating the new organism. Sometimes it is difficult to isolate any organism from an infective focus or those isolated are of no use as vaccines. In these cases, the best results are obtained with stock vaccines. The advantages of autogenous and stock vaccines have already been discussed.

In some cases it is not enough to stimulate the defence mechanism of the body by vaccines alone but steps should be taken to ensure phagocytosis and the access of antibodies to the foci of infection. For example in the case of chronic abscesses vaccines by themselves will do no good unless the abscess is opened and evacuated as well. Where the useful co-operation of an experienced bacteriologist is not available the general practitioner should in the best interest of his patient keep himself in touch with the latest advances in vaccine therapy. It cannot be overemphasized that a properly prepared vaccine should be considered as a potent substance capable of causing much harm to the patient when wrongly used. Before the administration of a vaccine all these points should be carefully considered. In competent hands results are very encouraging in cases of localised infections and evidence is gradually accumulating to show that vaccine may also do good in generalised infections as well.

A few words may be said about the value of different preparations of vaccines. The simple vaccine consisting of killed cultures suspended in saline is perhaps the best and gives the most consistent result. As regards the other modes of preparation it is very likely that the antigen is altered as a result of the elaborate process necessary for the preparation in addition to the risk of contamination. The ideal vaccine would be one in which all the useful antigenic components of the bacteria are in solution. This can be properly standardised and therefore allows the actual effective dose of the vaccine to be more accurately measured. The reduction of toxicity of certain

vaccines by means of chemicals such as formalin is being more generally practised now and should be of much value in future.

The following is a brief outline of the more important vaccines used either in prophylaxis or treatment of diseases.

Typhoid Vaccine. It is a mixed vaccine consisting of a carbolised saline suspension of three organisms, *Bact. typhosum* 1,000 millions, *Bact. paratyphosum A* 500 millions and *Bact. paratyphosum B* 500 millions per c.cm.

For prophylaxis it is given subcutaneously in two doses of 0.5 c.cm. and 1 c.cm. at an interval of 7 to 10 days. Some people prefer to give a third injection after 7 to 10 days. For children the dose is proportionately reduced according to age.

This vaccine has been used extensively in the British Army since 1909 with very good results. The immunity lasts for about a year, and revaccination with a single dose of 1 c.cm. should be done every year. Intravenous inoculation of typhoid vaccine has been tried recently with very encouraging results. The immunity is said to last longer in these cases but owing to the danger of protein shock this method is not recommended.

Oral administration of vaccine has been extensively used in South Africa. The vaccine is given as a suspension in teaspoonful doses, or it can be made into a pill. Three doses each of 45,000 million organisms combined with ox bile in keratine-coated pills can be given. The results of oral administration are however inconclusive.

In the treatment of typhoid fever vaccines have been used with success. An initial dose containing 100 million organisms is given subcutaneously and subsequently three to four days apart, increasing the dose gradually; if sensitized vaccine is used this should be given daily for four days in doses of 500 to 1,000 million organisms subcutaneously or 100 to 200 million intravenously. From the available evidence it appears that typhoid vaccine may favourably influence the course of the disease, but it has been argued that the same results can be obtained by giving any other bacterial vaccine, and that the action obtained is most probably non-specific in character.

Bacillary dysentery. Two types of organism are mainly concerned in this infection, *Bact. shigæ* and *Bact. flexneri*. *Bact. shigæ* is a very toxic organism producing an exotoxin whereas *Bact. flexneri* is relatively non-toxic. On account of the toxicity of the Shiga type various attempts have been made to reduce the toxicity of these strains for the preparation of vaccine. For this purpose Boehncke (1917) introduced a toxin and anti-toxin mixture, which he called 'Dysbakta.' For prophylaxis this was used by Bischoff (1918) in doses of 0.5, 1.0, and 1.5 c.cm. at five days' intervals with great success.

Recently, formalised vaccine (anacultures) have been used with success but it has not as yet been tried extensively enough to enable one to assess its real value in prophylaxis. Vaccination against dysentery with oral administration of Besredka's bilivaccine is recorded to have given good results but they are not so uniform as in the case of subcutaneous injection.

In the case of *Bact. flexneri*, the preparation of a vaccine is much less difficult as it is nontoxic. Except that the vaccine should contain all the representatives of various antigenic groups there is no other precaution necessary in the preparation of the vaccine. The usual prophylactic dose is 250, 500 and 500 millions at weekly intervals.

Treatment of bacillary dysentery by means of vaccines is used especially in chronic cases. Opinions as to the efficacy of vaccine in such condition are very divergent but Nolf (1919) and Acton and Knowles (1924) report favourable results with autogenous and stock vaccines.

In the beginning vaccines may be given subcutaneously or intracutaneously starting with small doses such as 10,000 to 1,000,000 organisms and increasing to as high as 5 to 10 million organisms. Some clinicians have reported striking results in chronic cases with intravenous doses every fourth or fifth day and gradually increased from 5 to 60 million organisms. It has also been tried in combination with 150 to 200 c.cm. of water per rectum by the drop method. Polyvalent vaccines have also been tried by the mouth. Doses recommended are 20 to 30 drops on the first day, 50 drops on the second day and 60 to 70 drops on the third day. Vaccines in the form of tablets have been prepared for use during epidemics. Each tablet contains 100,000 organisms and 5 or 6 tablets may be given daily dissolved in water or sodium chloride solution. The results of vaccine treatment have varied greatly in the hands of different observers.

Cholera vaccine. It is only used for prophylactic purposes. The vaccine consists of 24 hours culture of the cholera vibrio suspended in normal saline, killed by heat at 56°C. for half an hour and 0.5 per cent. phenol added as a preservative. Vaccines prepared in India contain 8,000 million organisms per c.cm. and the usual prophylactic doses are 0.5 c.cm. and 1 c.cm. at an interval of a week. A third dose of 1 c.cm. may be given but is thought to be unnecessary. Sometimes cholera vaccine is mixed with T. A. B. vaccine to produce immunity against all simultaneously. In emergency when two doses cannot be given, a single dose of 8,000 millions will give rise to sufficient protection.

In the prophylaxis of cholera, extensive observations were made in India by Russell. He found that in the comparative trial of cholera bilivaccine (oral) and the ordinary cholera vaccine (subcutaneous), both conferred a high degree of immunity. Russell expressed the opinion that the subcutaneous method was superior, and was able to show

that five days after a single subcutaneous dose of cholera vaccine the immunity was about as high as that present three days after a full course of the oral vaccine.

Plague vaccine. Statistical evidence from different countries shows that vaccination against plague reduces the incidence and case mortality markedly. Haffkine's vaccine is used extensively in India. It is prepared by growing *Past. pestis* in goat-meat-digest-broth at 25° to 30°C. for 2-6 weeks, then killed by heat for one hour at 60°C. and 0.5 per cent. phenol added as a preservative. Schutze claims to have got better results in animal experiments by using cultures grown at 37°C. Flu (1929) prepared a vaccine from a culture of *Past pestis* dissolved by bacteriophage and heated to 44°C. for 4 hours in the presence of 0.5 per cent. phenol and claims to have got very good results in animals. In view of the above experiments bacteriophage lysed vaccine and Schutze's vaccine are worthy of trial in human subjects.

Two doses of the vaccine are generally given for prophylaxis, the first dose being 2 c. cm. and the second 4 c. cm. The interval between injections is 10 days. The results obtained from the use of this vaccine are quite convincing. In one very well controlled study in Bombay, it was found that while the incidence in the unvaccinated was 8 per cent., in the vaccinated it was only 1.3 per cent. and as against a mortality rate of 4.7 per cent. in the first group the rate was only 0.4 per cent. in the second.

Lobar pneumonia. A considerable amount of work has been done in recent years on the value of vaccines in the prophylaxis and treatment of lobar pneumonia and workers are unanimous that administration of pneumococcal vaccine confers a high degree of immunity in susceptible animals. The immunity is type specific so that in the preparation of a prophylactic vaccine all the common types have to be included. According to the recent work of Griffith on the variability of the types of pneumococcus there is a possibility of change in types after repeated mass inoculation so that the vaccine has to be changed accordingly.

The administration of such a vaccine for prophylactic purposes has proved to be of great value in mining areas in Africa and in the Army where the death rate used to be very high before the use of such vaccines.

For prophylaxis, three doses are given subcutaneously at weekly intervals, each dose consisting of 1,000 millions of each of the most common types of pneumococci. Dubos and Avery (1931) isolated a highly specific enzyme from a bacillus capable of decomposing the specific polysaccharide of type III pneumococcus. Animal experiments showed that it is effective both as a prophylactic and therapeutic agent in an infection with type III pneumococcus, but no conclusive experiment has been done on human subjects. It has been observed that in an epidemic of lobar pneumonia there is often a change in the bacterial flora. Other

organisms such as hæmolytic streptococci, *H. influenza*, staphylococci and *Nisseria catarrhalis* are frequently found either in addition to or in the absence of pneumococci. It is therefore better to prepare a mixed vaccine for prophylaxis. It should be noted that there is a limit to the varieties of organisms which can be included in the vaccine. When a large variety of strains are included in the vaccine it may not be possible to give a sufficient number of each to produce immunizing response.

As regards the treatment of lobar pneumonia with vaccine it has been seen that if administered early it influences the course of the disease so that combined with the serum treatment it may be of great help. Minor pneumococcal infections such as the common cold with bronchitis, chronic sinusitis and other nasal inflammations if unattended with any other pathological condition, *e.g.*, deviated nasal septum, polypus, etc., are benefited by the administration of a pneumococcal vaccine. Where possible, autogenous vaccine should be employed but stock vaccine is also of benefit. In this condition the initial dose is 10 million organisms increased every 3 or 4 days, up to 100 millions, after this it is increased by 100 millions at weekly intervals. For prevention of exacerbations monthly injections of 100 millions should be continued during the winter.

Whooping cough. Results have been very variable with the use of this vaccine in the past when the importance of freshly isolated cultures was not recognised, but with the use of fresh cultures the results will most probably be better in future.

The following is a schematic representation of dosage of the vaccine for prophylaxis in millions of *H. pertussis* (from Fleming and Petric, 1934).

		1st dose.	2nd dose.	3rd dose.
Under 1 year	..	400	800	1,600
1 to 2 years	..	800	1,600	3,200
3 to 5 years		1,200	2,400	4,000
5 to 10 years	.	1,600	3,200	4,000
Over 10 years	..	2,000	4,000	4,000

For treatment mixed vaccines are better than vaccines consisting of only *H. pertussis*. A combination of 500 millions of *H. pertussis* with 250 millions of *H. influenza* and 20-100 millions of pneumococci per c.cm. is very suitable. This is given every day or every 2 days to a child of five or six years in doses of from 0.2 c.cm. to 1 c.cm. Cockshut claims to have got extremely good results by the use of doses, 4 to 10 times of those recommended.

Influenza. During the last influenza epidemic extensive trials were made on the efficacy of a mixed influenza vaccine consisting of *H. influenza* 500 to 1,000 millions per c.cm., pneumococcus 1,000 millions per c.cm. and streptococcus 100 millions per c.cm. The dose is 0.25, 0.5

and 1 c.cm. at an interval of 4 to 7 days. The results as reported are extremely conflicting. Immunity does not last more than three months.

Acute rheumatic fever. Vaccine treatment of this condition with hæmolytic streptococci has given favourable results especially in checking the recurrences which are so common in this condition. Collis and Sheldon (1932) used weekly doses commencing with 200,000 cocci followed by 500,000 and then continued as follows:—1, 2½, 5, 10, 15, 20 millions followed by a gradual increase by 10 millions till 100 millions have been given. They administered the vaccine intravenously with safety.

Chronic rheumatic conditions. These include various forms of non-specific arthritis, fibrositis, perineuritis, etc. Various attempts have been made to treat these cases with vaccines prepared from organisms isolated either from the site of the lesion or from a septic focus in the teeth, tonsils, nasal sinuses, genito-urinary or intestinal tracts. Although it is very difficult to correlate the finding of organisms from such septic foci and the occurrence of rheumatic conditions yet it has been seen that vaccines prepared from them are able to alleviate or cure the condition in a large number of cases. Vaccine treatment should be auxiliary to any radical measures necessary for the removal of an infected focus. Autogenous vaccines are better than stock vaccines in these cases but the vaccine should be prepared by an expert. A stock vaccine for such conditions should contain a large number of strains from the mouth, tonsils, intestine and genito-urinary tract isolated from rheumatic cases.

The Arthritis Committee of the British Medical Association (1933) recommends an initial dose of 20,000 to 50,000 organisms when a septic focus is suspected or half a million when no septic focus exists. The doses are gradually increased every five or six days and it is rarely that a case will require a dose of more than 10 millions.

Acne vulgaris. This condition is due to a mixed infection with the acne bacillus and the staphylococcus. Vaccines prepared from both these organisms have been found to be of benefit in such conditions. The treatment should be continued for a long time to get any good result. Autogenous or stock vaccines may be used. The stock vaccine should contain both types of organism.

For therapeutic purposes mixed staphylococcus and acne vaccines are used. The dose of staphylococcus is from 200 millions gradually worked up to 2,000 millions. Acne bacillus is best given in an initial dose of 5 millions followed at weekly intervals by doses of 7½ and 10 millions. If there is no improvement with these, the dose should be increased to 100 millions, and should be followed by increases of 100 or 200 millions up to 2,000 millions. As the acne bacillus is but slightly toxic and very seldom gives rise to general reactions these large doses can be given with safety. Sometimes it is mixed with intestinal streptococci especially in cases where there is a preponderance of streptococci in the intestine. The dose used is similar to that of the acne bacillus. This

treatment should, of course, be combined with suitable medicinal, dietetic or physical treatment and regular evacuation of the contents of acne pustules and removal of comedones.

Furunculosis. Staphylococcus vaccine was the first vaccine used for therapeutic purposes by Wright. Usually staphylococci isolated from boils are antigenically similar so that there is very little difference between the use of a stock vaccine and autogenous vaccine. Vaccine in the treatment of furunculosis serves two purposes. Not only does it cure the condition but it also prevents the recurrence of this condition anywhere else in the body.

Large doses are recommended for indolent boils to produce a focal reaction which is beneficial in such cases. The usual dose in a severe case is 100 to 2,000 millions of staphylococcus. In less severe cases 200 or 300 millions may be the initial dose, increased at intervals of 5 to 7 days up to 1,000 or 2,000 millions. Usually six to eight doses are sufficient to cure even very chronic cases. But, failing with this vaccine, streptococci isolated from faeces or boils may be combined with this vaccine.

Recently, Gratia (1930) has used a vaccine in which staphylococci were dissolved by certain streptothrices and moulds. This he calls *mycolysates* which are very beneficial in chronic cases. Bacteriophage lysed vaccines are also in use but the results so far are indifferent. As a result of the recent isolation of a powerful exotoxin from staphylococci, it is being used in modified form (toxoid) for the treatment of boils. This toxoid is prepared by incubating the toxin with 0.3 per cent. formalin for 2 days and injecting subcutaneously commencing with a dose of 0.05 c.cm. and increasing the dose every five to seven days by 0.05 c.cm. Although still in the experimental stage, the results so far obtained are very encouraging.

Coliform infections. *Bact. coli* vaccines are used both for prophylactic and curative purposes. For prophylaxis they are used in patients suffering from coliform infections of the urinary tract preparatory to a major operation of the genito-urinary tract. Cases for such treatment should be carefully chosen as there may be acute symptoms of coli fever following an initial dose in cases where there is an obstruction to the outflow of urine. The doses recommended are 100, 500 and 1,000 millions at weekly intervals.

For therapeutic purposes these vaccines are used for cases of bacilluria and pyuria which are resistant to ordinary treatment and in which no exciting cause can be found.

The initial dose in children over 5 years should be 20 millions, increased at weekly intervals to 500 million organisms. In adults the initial dose is 25 millions, increased gradually at weekly intervals to 2,000 millions if there is no focal or general reaction. Acute infections due to late lactose fermenting coliform bacilli are also treated with such vaccines. The initial dose of 25 millions should be given about

5 days after the temperature has returned to normal, the dose being increased gradually to 500 or 600 millions at weekly intervals.

Ulcerative colitis. Recently, a special type of diplococcus has been isolated from ulcers in cases of ulcerative colitis and vaccines prepared from such organisms either alone or combined with an antibacterial serum have been found to be of great benefit (Bargen 1924). The treatment however should be combined with strict attention to diet and removal of septic foci. The vaccine is prepared by culturing the cocci in broth for 48 hours, adding 0.4 per cent. tricresol to the culture to sterilise it and the concentration adjusted to 2,000 millions per c.cm.

An initial dose of 200 millions is given and if it is not followed by any reaction the dose is increased every third day up to the maximum dose of 2,000 millions per c.cm. Sterile filtrates of cultures of the organism have also been used, the maximum dose being 1.15 c.cm. of such filtrate.

Gonococcal infections. The use of such a vaccine has been of the greatest value in cases of complications resulting from an infection with gonococci, but used with caution it can be helpful in all stages of gonorrhœa. In the early stage it reduces the duration of primary infection and diminishes the number and severity of the complications. It is used in complications such as arthritis, epididymitis, orchitis, etc. According to the recent work of Torrey, gonococci are composed of many antigenically varying members so that any vaccine to be of use should either be autogenous or should contain a large number of these strains.

Various different vaccines have been used for the treatment of such conditions but the most commonly used is the simple vaccine prepared from freshly isolated cultures grown on serum agar. Mixed vaccines have been used in some cases consisting of staphylococcus, streptococcus or diphtheroid bacillus along with polyvalent gonococcal vaccine.

Only small doses are tolerated, and it is best to avoid any reaction. The dose also depends on the severity of the illness. In acute complicated cases it is advisable to begin with 500,000 organisms and gradually work up to 10 millions. In chronic cases the initial dose should be small but the amount administered may rapidly be increased up to 500 millions or more so long as there is no reaction.

Asthma. True asthma is a result of hypersensitiveness to some foreign protein. There are, however, many cases in which this is associated with bacterial infection and it is in these cases that vaccine therapy has been found to be of considerable value by many workers. Either autogenous or stock vaccines can be used. For autogenous vaccine organisms such as *H. influenzae*, pneumococcus, streptococcus or *Bact. friedlander* are obtained from sputum culture. In a certain percentage of cases refractory to such vaccines, organisms isolated from the intestine, particularly enterococci, are incorporated in the vaccines with great benefit. In determining the sensitiveness to the

various organisms isolated either from the sputum or intestine, dermal reactions are of great help.

The initial dose should always be small in order to prevent the precipitation of an attack. The initial dose of streptococci, 0.1 to 0.5 million are used, increased by 0.1 million up to 1 million and further continued, where necessary, to as large a dose as can be tolerated by the patient.

If there is reaction with any dose, the next one is reduced and further increase in dosage should be made with great caution. Freeman advocates 0.5 c.cm. of adrenalin mixed with the vaccine to avoid reactions.

Smallpox. The vaccine used for prophylaxis is a living attenuated virus and of all prophylactic vaccinations this is perhaps the most useful. According to reliable authorities vaccination has very appreciably reduced the incidence and the mortality rate of smallpox.

The vaccine is available in this country only in certain government laboratories and municipal vaccine depots. It consists of a glycerine emulsion of scrapings of pustules from calves inoculated with the smallpox virus.

The technique of vaccination. The skin of the forearm or upper arm is cleaned with soap and hot water and dried with a clean towel (no antiseptic is used). Two drops of the vaccine lymph are placed on the site of inoculation and the part is gently scratched with a lancet over an area of half an inch by one-third of an inch, care being taken not to draw any blood. The excess of the lymph is allowed to dry on the skin.

Rabies. This vaccine has been found to be very successful for prophylaxis. The principle of vaccination in this case is the immunization of the affected person during the period of incubation which is fairly long.

The vaccine consists of a one per cent. emulsion of the brain of infected rabbits or sheep, which have died of fixed virus infection, in 0.5 per cent. carbolized saline solution. The treatment with this vaccine is rather severe and the course is prolonged; 5 c.cm. of the above vaccine is injected subcutaneously in the flanks daily for 14 days. Certain complications due to hypersensitiveness may follow. It is claimed that the use of this vaccine has reduced the mortality rate of rabies considerably.

Diphtheria. In the past no method was known of immunizing children against diphtheria but with the increase in our knowledge on immunity various methods have been adopted for immunizing children against this disease. Until recently, toxin anti-toxin mixtures were used for prophylactic purposes but it has been found that the presence of active toxin in such mixtures is liable to give rise to accidents owing to carelessness in the preparation, storage, etc.

The recommendations of the Ministry of Health for immunization should be followed. They recommend that immunization should be

preceded by a Schick test to exclude children who are already immune. Positive Schick reactors who have simultaneously been tested for hypersensitiveness to toxoid and found to be negative, should be immunized by subcutaneous injection of formol toxoid in doses of 1 c.cm. on three occasions with fortnightly intervals. Another Schick test should be done some months after immunization to ascertain the development of immunity. The most suitable age for such immunization is between one and three years as very few children are hypersensitive to toxoid at this age and it is given at a period when they are most liable to infection. Children below one year need not be immunized.

SERUM THERAPY

The practice of serum therapy, began with the remarkable discovery of von Behring and Kitasato (1890) who showed that the sera of animals that had received injections of tetanus and diphtheria toxins had the property of neutralising these toxins and could prevent their poisonous effects. Following upon their discovery, Pfeiffer (1894) demonstrated that cholera vibrios, when introduced into the peritoneal cavity of immunized guinea-pigs, were killed and lysed. These observations lent support to the view that the blood sera of immunized animals contained protective substances which on being transferred to infected animals would help the latter to overcome the infection. Later on, attempts were made to prepare antisera against various bacterial infections and they were tried in the cure and prophylaxis of the corresponding bacterial diseases.

Although it was hoped in the beginning that antisera of high therapeutic value could be prepared against various bacterial infections by immunizing animals, the experience of the past four decades has proved to the contrary. The reasons are not far to seek. There are various virus diseases, *viz.*, small-pox, chicken pox, measles, etc., where the pathogenic organisms have not been culturally isolated in suitable antigenic forms, while there are others, *viz.*, typhoid, cholera, etc., in which though pathogenic organisms can be isolated, they fail to produce antisera of any therapeutic value.

A careful study of the available data reveals that the value of antisera varies with the type of the serum (whether anti-

toxic or antibacterial) and the time of administration in the course of the disease. For prophylaxis the usefulness of antisera seems to be limited. The protection they afford is only for a short period (4 to 6 weeks) owing to the rapid elimination and disappearance of antibodies from the blood. As a therapeutic agent the use of antitoxins is extremely helpful, especially in diseases like diphtheria where the toxin circulating in the blood is directly neutralised by the antitoxin, provided it is given early and in adequate dosage.

On the other hand, antibacterial sera are not of as much prophylactic or therapeutic value as the antitoxic. This is because such sera act partly by the presence of specific bacteriolysins, precipitins, etc., and partly by the mobilisation of the nonspecific immunity mechanism. Hence a higher concentration of antibodies in the serum does not necessarily mean greater efficiency. Still the administration of potent antibacterial sera in the early stages of severe bacterial infections, such as, Felton's antipneumococcus serum in type I pneumonia, polyvalent antimeningococcus serum in cerebro-spinal meningitis, in most cases cuts short the course of the disease and prevents unfavourable complications. It may, hence, be concluded that although the sphere of usefulness of antibacterial sera is limited, they are of considerable therapeutic value in certain selected cases.

Types and preparation of antisera. The antisera in common use may be divided into three types:

(1) Antitoxic sera, (2) antibacterial sera, (3) antiviral sera.

The methods of preparation of these are different and may be described briefly as follows:—

Antitoxic sera. These are prepared by immunizing horses by repeated inoculations of formalised toxins (0.2 to 0.4 per cent. of formalin added to the crude toxic filtrate and incubated at 37°C for from 4 to 6 weeks). The serum is obtained from such animals and standardised in terms of antitoxic units as prescribed by the official control authorities such as the Permanent Commission of the Health Organisation of the League of Nations. Official control also exists in most of the countries to regulate the standard of purity and potency of therapeutic sera.

Unfortunately there is no such control in India. The important and frequently used antitoxic sera are tetanus antitoxin, the diphtheria antitoxin, antivenin, etc.

Antibacterial sera. These are prepared by immunizing horses or other suitable animals by repeated inoculations of organisms. The antigen in this case consists of a suspension in physiological saline of the bacterium either living or killed, which contains both bacterial protein and endotoxin. The serum of the immunised animals contains antibodies against both. According to our recent knowledge on the antigenic diversity in certain types of organism and the extreme specificity in the action of the antisera prepared from such antigens, great care is necessary in the proper choice of antigen in the preparation of these antisera. In the preparation of a polyvalent antiserum, the different type specific sera are prepared separately and then are mixed together. Although by this method there is some weakening of potency due to the ultimate dilution of each type, it has been found to be better than the simultaneous injection of a variety of antigen which results in a low titre of antibody. The titration of such sera is done by estimating the different antibodies, *e.g.*, agglutinins, tropins, complement fixing antibodies, etc. or by animal experiments. Examples of sera mainly antibacterial are the anti-streptococcal, anti-dysenteric, anti-pneumococcal, anti-meningococcal, anti-plague, etc.

Antiviral sera. In certain diseases like measles or poliomyelitis, the causative organism is not known and cannot be cultivated *in vitro*, but there is ample evidence to show that immune bodies appear in the blood during the course of such virus infections. These immune bodies can exert a prophylactic and some curative action. Recently, therefore, the sera of patients recovered from such infections have been used for prophylaxis and curative purposes with favourable results. Patients free from tuberculosis, syphilis, or other infectious diseases are selected for this purpose and 500 c.cm. of blood from an adult or 100 c.cm. of blood from a child are obtained under sterile conditions, the serum separated, filtered and preserved by addition of 0.5 per cent. carbolic acid or 0.39 per cent.

of tricrosol. If kept in an ice chest, they retain their potency for months. Such convalescent sera are used in measles and poliomyelitis. Recently, convalescent smallpox serum has been used with very promising results in cases of encephalitis following vaccination. It has also proved to be possible to immunize animals against virus infections and thereby to obtain a serum capable of influencing the course of the disease against which the animal has been immunized.

The concentration of sera. It has been found that the bulk of the antitoxin is associated with the pseudoglobulin fraction of the protein, whereas protective substances in antibacterial and antiviral sera are associated with the euglobulin fraction. The different proteins of the serum, the euglobulin, the pseudoglobulin and the albumin, have different degrees of solubility in neutral salts. By adding appropriate concentrations of ammonium or sodium sulphate to the serum or plasma, different serum protein fractions can be separated for the purpose of concentration and purification of the sera. The advantage of such concentration and purification is that considerably larger quantities can be administered without the risk of foreign protein shock.

Storage and deterioration of sera. Sera must be kept in the dark and in the cold. The potency of most sera is maintained for a period varying from a year to two years after which there is a decline in the number of units of antitoxin in it, and if due allowance is made for this deterioration, sera may be used which have been kept for long periods than the time limit on the labels.

Modes of administration. The choice of the route by which an antiserum should be administered is a very important consideration because upon it depends the rapidity of absorption of antitoxin or other antibodies. For prophylaxis where rapid absorption is not a necessity, antisera are usually administered subcutaneously. But the proper choice of route in the therapeutic use of an antiserum is of the greatest importance. There are various routes through which an antiserum may be administered of which the following are the most commonly chosen. Subcutaneous, intramuscular, intravenous, intrathecal,

and other less commonly used routes are intraperitoneal, intracisternal, intraventricular, oral or rectal. The best route to be adopted in a particular case depends on the nature of the illness and the type of the antiserum, the severity of the illness, the stage of the disease at which antiserum is being administered, the age of the patient, etc.

Subcutaneous. This is the route commonly used although it is neither the best nor the most effective; for prophylaxis it is used very commonly. For therapeutic purposes, particularly in severe toxæmic cases, where rapid neutralisation of toxins is desirable, it is worse than useless, because the antibodies inoculated are absorbed too slowly to attain quickly the necessary concentration in the blood. The belief that this route is safer than the intravenous route has not also been substantiated by experimental evidence.

Intramuscular. This route is preferable to the subcutaneous and should be more widely practised. When sera are given by this route antibodies are rapidly absorbed and reach a high concentration in the blood in a comparatively short time.

Intravenous. This is the best route for administration of antitoxin where the aim is to get a direct neutralisation of the toxins circulating in the blood. In acute and severe cases where toxæmia is great and delay dangerous, the initial doses of serum should be given intravenously as a routine procedure followed by intramuscular or subcutaneous injections for the subsequent doses. Experience has shown that this route is not generally more risky than others if the serum is given diluted with normal saline and at body temperature.

Intrathecal. This route is preferable in diseases such as cerebrospinal fever, tetanus and poliomyelitis where it is desired to obtain the highest concentration of antibodies in the focus of infection. A lumbar puncture is performed under local anaesthesia and an amount of cerebrospinal fluid equal to or slightly more than the amount of serum to be injected removed and the serum allowed to run into the theca by gravity or by injection with a syringe. The quantity of serum given at a time is generally 20 to 30 c.cm. for an adult.

Intraperitoneal. Platou (1923) used this route in severe cases of diphtheria in infants where it was difficult to obtain suitable veins for intravenous injection. It has also been recommended by other workers and is said to be safe and well tolerated by the patients, but it has not been used much on account of the apparent risk of trauma or sepsis.

Intracisternal. This route of administration of sera has been employed to a considerable extent lately, especially in America in the treatment of cerebrospinal fever (Goldman and Borwer, 1931). It appears to be free from danger but should not be undertaken without

previous practice on the cadaver. The route is particularly suitable in cases with spinal subarachnoid block.

Intraventricular. This method has not been much used and it is doubtful whether the results are encouraging. Neal prefers this route to the cisternal route in cases with spinal block. In young infants ventricular puncture is best performed through the anterior fontanelle and the method is particularly useful in infants with a patent anterior fontanelle.

Oral. Although it has been shown that certain antisera are capable of exerting their specific effects when given by the mouth, the oral route is unquestionably the least effective. If this route is chosen at all, as for example in young infants, the serum should be diluted and given on an empty stomach in repeated doses.

Rectal. This route, although equally ineffective, is sometimes chosen to avoid serum reactions and discomfort following repeated inoculations. The rectum is cleared by an enema, the serum diluted with normal saline, made up to about 4 to 5 oz., warmed to body temperature and given high up with the help of a catheter.

Reactions following administration of serum. Parenteral administration of a foreign protein is sometimes followed by certain reactions. These are usually of moderate severity and do not constitute any danger to life. The factors that bring about such unpleasant reactions are bound up in part with the serum, irrespective of the specific antibody it may contain and in part with the degree of sensitiveness to the foreign protein of the person receiving it. The following are the common reactions met with.

In most cases the injection of antiserum is followed by only slight reactions, such as local pain and tenderness accompanied by mild fever which passes off in 24 to 48 hours. In a small percentage of cases, however, more severe reactions may follow.

Protein shock. This is generally observed after intravenous injections of large quantities of serum and is ascribed to the effect of foreign protein introduced. The reaction sets in within 15 min. to an hour and is characterised by chill, dyspnoea, cyanosis, rise of temperature, followed later by a fall of temperature to normal or subnormal, profuse perspiration and rapid pulse. The symptoms generally pass off without any treatment, but when they persist an injection of adrenalin

0.5 c.cm. or atropine 1/120 gr. subcutaneously is all that is needed to restore the patient to normal.

Serum sickness. This complication is seen in some persons about 8 to 10 days and sometimes even earlier, after the injection of serum. It is characterised by urticarial rash, pruritus, pyrexia, swellings of joints and lymphatic glands, malaise, oedema and albuminuria. The incidence and severity of serum sickness increase with the age of the patient. The frequency of reaction is said to be less after intravenous than after intramuscular injections, and serum of some horses is particularly liable to produce these reactions. The reason for this is unknown. The reaction is rarely severe and needs only symptomatic treatment. Calcium lactate in 10 gr. doses 3 or 4 times a day is beneficial; antipruritic lotions such as calamine lotion with 1.0 per cent. carbolic acid relieve itching; aspirin 5 to 10 gr. by the mouth reduces pain and pyrexia. When it is intended to give large doses, it is inadvisable, in order to avoid these unpleasant complications, to use concentrated sera in preference to ordinary sera. The incidence of this condition has been considerably reduced since the introduction of concentrated sera.

Anaphylaxis. This is one of the dreaded dangers that often dissuades the practitioner from using serum or giving it by the intravenous route. Anaphylaxis has undoubtedly been the cause of some fatalities, but it should be realised that the likelihood of its occurrence is remote, its incidence according to Park (1928) being only 1 in 20,000 and fatality 1 in 50,000. It can be avoided if a little care is taken and the case is studied before injection.

Some persons are extremely sensitive to the administration of a serum. These may be divided into two groups.

(a) Carriers of an hereditary allergic factor, *e.g.*, horse asthmatics who react almost immediately following the administration of a dose of serum.

(b) Persons sensitized by previous injection of a serum. The risk of death from allergic shock is very slight. But the administration of serum intravenously to horse asthmatics is more dangerous than to persons previously sensitized to serum

Although there is no risk of death the symptoms are sometimes alarming, characterised by a sudden onset, about a quarter of an hour after the introduction of the serum with restlessness, anxious expression, pallor, perspiration, rapid feeble pulse, deep and laboured respiration followed by cyanosis, unconsciousness, muscular twitchings, rigors, convulsions and involuntary micturition and defæcation. For this reason it is necessary to test the sensitiveness of a patient by intracutaneous injections of 0.05 c.cm. of 1 in 10 diluted serum. If after 10 to 20 minutes the resulting wheal increases in size and shows a zone of erythema the reaction should be considered positive. The degree of sensitivity depends on the extent of the wheal and reactions with pseudopodial projections are indicative of an extreme degree of sensitiveness. In America the conjunctival test is preferred to the intracutaneous test. It is said to be a more sensitive test but unfortunately is associated with the risk of damaging the cornea in hypersensitive subjects.

In such cases desensitization has to be carried on to allow introduction of serum in large quantities. This can be effected by (1) partition of the dose, and (2) slow administration of the serum.

In sensitive persons 0.01 c.cm. of serum is given subcutaneously and this dose is doubled every thirty minutes till 1 c.cm. in all is given. After half an hour 0.1 c.cm. is given intravenously and then doubled every 20 minutes till the full dose is administered. If there are any allergic symptoms at any time, the previous dose should be repeated instead of increasing the dose further. Administration of the serum may be preceded by an injection of 1/150 to 1/100 gr. atropine and adrenaline chloride solution (1 in 1,000) is kept ready for emergency purposes in case it is needed. The serum is given very slowly warmed and diluted to body temperature. When anaphylaxis comes on in spite of due care, symptomatic treatment should be given. Injections of adrenalin, pituitrin and atropine are useful. Inhalations of amyl nitrite or inhalations of oxygen may help.

Febrile reactions after intravenous injections of serum.
The reaction occurs about an hour after the intravenous dose and

is characterised by rigor, increase in cyanosis in pneumonia cases, profuse sweating and a fall in temperature. It is not a serious complication. Care should be taken to use sterile distilled water for the preparation of normal saline necessary for diluting the serum.

Neurological complications of serum treatment. Although they are rarely met with, the presence of these complications has been recognised lately. They may be classified into four groups (Allen, 1931). (1) A radicular type, resembling an Erb-Duchenne paralysis of acute onset; (2) a neuritic type, in which single nerve trunks are affected; (3) a polyneuritic type in which the clinical condition resembles that of a toxic polyneuritis; (4) a cerebral type in which the prominent features are probably referable to intracranial α -dema.

The condition has most often followed the use of tetanus antitoxin and the symptoms have appeared a few days after an attack of serum sickness. The patient complains of intermittent stabbing pains in one or more segmental areas or in the distribution of a peripheral nerve. Muscular weakness and wasting follow. This condition may persist for months but prognosis in such cases is generally good.

Dosage of antisera. The dose is dependent on so many factors that there cannot be any generalisation in the question of dosage. It depends on the type of serum, the severity of the disease, the period at which it is administered and the age of the patient. Each case is judged on its own merits; dosage has been discussed when dealing with the different antisera.

Antitoxic and Antibacterial Sera

Diphtheria antitoxin. This is obtained by immunising horses against diphtheria toxin. Only the exotoxin is used for immunising purposes. Such a serum is capable of directly neutralising the diphtheria toxin.

There cannot be any universally accepted scheme of dosage as in various diseases the interval elapsing between the onset of the disease and the time of administration of the serum have all to be considered. The following two tables of dosage given by experienced authorities are perhaps the best guide to a system of dosage which adequately represents our scientific knowledge and clinical experience.

The following table modified from Park and Williams (1934) gives the units of antitoxin to be administered to cases of varying grades of severity.

		Route	Dosage	
			Children weighing up to 50 lbs. (under 15 years of age)	Children and adults weighing 50 lbs. and over.
Mild	cases	Intramuscular.	3,000—5,000 units	5,000-10,000 units
Moderate	,,	,,	5,000—10,000 ,,	10,000-15,000 ,,
Severe	,,	Intravenous* or intramuscular and intravenous.	10,000- 20,000 ,,	20,000- 0,000 ,,
Malignant	,,	Intravenous*	15,000—30,000 ,,	30,000-60,000 ,,

*When given intravenously one-half the amounts stated.

Cases of laryngeal diphtheria, moderate cases seen late at the time of the first injection, and cases of diphtheria occurring as a complication of the exanthemata should be classified and treated as 'severe' cases. In all cases a single dose of the proper amount, as indicated in the schedule, is recommended, or the following simple table of doses may be adopted.

Doses recommended are :—

	Mild	Moderate	Severe	Malignant
Children ...	4	8	16	32
Older ..	8	16	32	64
Route . .	IM	IM	IV	IV

(IM—intramuscular, IV—intravenous; the numbers refer to thousands of units of anti-toxin).

These are rough guiding doses and each case must be considered on its merits. The earlier the injection the more certain and rapid the effect—one large dose given early is far more efficacious than divided doses. It is easy to give too little but it is very difficult to give too much.

The mode of administration is of great importance, as the object in antitoxin treatment is to attain an effective concentration in the blood with the least possible delay. The ideal method therefore is the intravenous for all cases and the next best is intramuscular in which the rate of absorption is 3 to 6 times greater than the subcutaneous. Platon (1923) suggested the intraperitoneal route in cases where it is

difficult to find the veins particularly in infants and children. This route has not been chosen to any extent perhaps on account of the risk of trauma or sepsis. It is important to mention here the fact that the efficacy of antitoxin is greatest when given early in the attack and that it decreases as the day of administration is delayed.

Tetanus antitoxin. This antitoxin is capable of neutralising free toxin in the system but is ineffective against toxin fixed in the tissues. Therefore it is of the greatest value in prophylaxis and the therapeutic use of such a serum is necessarily very limited. The prophylactic use of such a serum not only prevents the occurrence of the disease but also influences the character and progress of the disease in patients who subsequently develop it, increases the period of incubation and the incidence of local tetanus, thus lowering the rate of mortality.

For prophylaxis, the amount to be injected depends on the severity and the degree of contamination of the wound as well as the interval that has elapsed since its infliction. 1,000 to 3,000 international units (500 to 1500 U.S.A. units) are given intramuscularly before any attempt to clean the wound by surgical methods is made. Ramon and Loeller (1927) recommended the following procedure: 10 c.cm. of antitoxin and 1 c.cm. of anatoxine (anatoxic formolised preparation) are administered at different places. Antitoxin is repeated ten days later and after another ten days 2 c. cm. of anatoxine is given. This method is said to afford protection in those patients who have incurred a risk of tetanus.

It is of much less value in the treatment of tetanus but there is general agreement that the system should be flooded with tetanus antitoxin at the earliest manifestation of tetanus. The following scheme of dosage recommended by the War Office Committee 1917 may be usefully followed:—

Day of disease	No. of international units to be given by		
	Subcutaneous route	Intramuscular route	Intrathecal route
1st day	...	16,000	32,000
2nd day	...	16,000	32,000
3rd day	...	8,000	...
4th day	...	8,000	...
5th day	4,000
7th day	4,000
9th day	4,000

Antistreptococcus serum. This serum is very extensively used now-a-days for the various infections associated with *Streptococcus hæmolyticus*. It is used in scarlet fever, erysipelas, puerperal sepsis, endocarditis, cellulitis and surgical infections. The value of its use in these various conditions is very difficult to assess. But from the available data it can be safely concluded that it undoubtedly influences the course and complications of the disease. It also favourably influences puerperal

infection and acute inflammatory and septic conditions when they are known to be associated with a hæmolytic streptococcus.

The serum is usually given by the intramuscular route in doses of from 10 to 50 c.cm. of a concentrated preparation, the amount varying according to the age of the patient and severity of the symptoms. To be of any use, it should be given within 4 days from the onset of the disease, with concentrated sera the reactions are less marked.

Antidysentery serum. The chief bacterial species calling for serum treatment in the order of their importance are the following:—*Bact. shiga*, and *Bact. flexner*. Although there is some divergence of opinion on the efficacy of antidysentery serum, there is considerable evidence of a general nature to support its use. The best results are obtained with the Shiga serum, but the results are quite satisfactory with the use of Flexner serum also. In the preparation of antidysentery serum (Flexner) all the types of antigens such as V.W.X. (Y) and Z should be included in immunizing horses. The Flexner serum consists of antibacterial element only whereas the Shiga serum is antitoxic. Some people are of opinion that the efficacy of the serum increases if there is a sufficient amount of antibacterial component in addition to the antitoxin. Although Shiga serum can be standardised, there is no method available to standardise the Flexner serum.

Serum for therapeutic purposes should be given early (12 to 24 hours after the onset of symptoms) and in adequate dosage to get the best results. In cases where the nature of the dysentery has not been diagnosed it is best to use a polyvalent serum. In cases of ordinary severity a single injection may be followed by remarkable improvement, but in severer cases the dose has to be repeated in from 12 to 24 hours, and again in 48 hours. In Shiga infection 3,000 to 4,000 units should be given in mild cases and 5,000 to 10,000 in more severe cases. Serum in strength of 1,000 units per c.cm. is generally obtainable, but the more concentrated preparations contain about 5,000 units per c.cm. The early stages of the disease are undoubtedly benefited by large doses of the serum and the death rate is low, but after the first week of the disease it is less effective and of no value in chronic cases. In patients suffering from severe toxæmia the best results were obtained by intravenous injection of 60 to 80 c.cm. of the Shiga serum followed by 150 to 300 c.cm. of normal saline, administered twice daily for the first two days and once daily for the next two days. In very toxic cases 5 per cent. glucose in distilled water is substituted for the saline. In less severe cases the intramuscular route is preferable to the subcutaneous route, which is painful, and the dose should not be less than 40 c.cm. in an adult and as much as 100 c.cm. may be given.

High rectal injections of 10 to 30 c.cm. of polyvalent serum after cleansing the bowels with 1.5 per cent. sodium bicarbonate and followed by starch and tincture of opium have also been tried. Intramuscular injections should be given at the same time. The varying results given

by the serum are probably due to the difficulty in standardising and the varying qualities of sera on the market.

Antipneumococcus serum. Of late the use of antiserum in the treatment of lobar pneumonia has been given much prominence. Opinions are however divided as to the efficacy of serum in the treatment of pneumonia, but sufficient evidence is available to show that the mortality rate of type I infection is reduced significantly in serum-treated cases (Cecil and Plummer, Park, Bullowa and Rosenbliith), and specific serum therapy is less efficacious in type II pneumonia. Two types of sera are available for this purpose.

1. Huntoon's antibody solution which contains antibodies against types I, II and III. Although clinical results are satisfactory with this serum, it gives rise to severe febrile reactions on intravenous injection, and its use is not recommended.

2. Felton's serum is a concentrated serum containing antibodies against type I and type II pneumococcus. It is so titrated that one unit is contained in that amount of serum which is capable of neutralising one million lethal dose of a virulent pneumococcus culture.

The use of such a serum reduces the temperature, pulse rate, respiratory rate and the toxæmia. The inflammatory change in the lungs is checked, but it has no influence either on the rate of resolution or on the complications.

The intravenous route is the method of choice for the administration of the serum. If there is any reaction it can be controlled by intramuscular or intravenous injection of 0.5 to 1 c.cm. of 1 in 1,000 adrenalin solution. The risk of allergic reaction following the first dose may be minimized by slowly giving 1 c.cm. of serum intravenously either pure or diluted with sterile normal saline. The rest of the dose is given after an interval of 20 to 30 minutes.

There is no uniform scheme of dosage, the dose depending on the severity of the case, and the time of administration in the course of the disease. Cecil advises an initial dose of 5 c.cm. followed in one or two hours by 15 to 20 c.cm. of the serum and a dose every 2 or 3 hours thereafter till 100,000 units have been given (usually 100 c.cm.). The doses are halved if the patient shows signs of improvement. An additional dose of 10 to 20 c.cm. may be given on the following day.

Antimeningococcus serum. It has been used extensively in the treatment of cerebrospinal fever for a long time. The earlier reports as to the efficacy of such a serum were somewhat exaggerated, but the present day opinion is that the serum, given early, controls the infective process and shortens the illness. The complications and sequelæ are much less; relapses are also less frequent and the disease does not continue so long. Although this is the usual experience with antimeningococcus serum, there are some cases where this form of treatment fails entirely. The reason for this is that the meningococcus consists of a heterogenous antigenic group and the serum to be effective

must be prepared from a large number of representative strains from these different antigenic groups. Further it has been seen that strains isolated from sporadic cases are different from the epidemic strains and sera prepared from such strains are of little therapeutic value in epidemics. The best method therefore would be to collect a surplus stock of the serum during an epidemic period and to use it for the next epidemic till organisms are freshly isolated and fresh sera raised.

There is no known method of titrating this serum. The experiments of McKenzie and Martin have shown that substances bactericidal to the meningococcus are present in increasing amounts in the serum of acute and chronic cases of cerebrospinal fever and the serum of convalescents. Encouraging results have been reported on efficacy of such a serum in the treatment of cerebrospinal fever but technical difficulties have hindered its trial on a large scale.

Daily intrathecal injections of from 30 to 60 c.cm. for an adult and 10 to 20 c.cm. for infants have been found to give satisfactory results. At least 4 doses in all should be given, but there cannot be any hard and fast rule about the dosage since it depends on the severity of the illness and various other factors. Two points should be noted in its administration:—(a) It should be given as early as possible, (b) the amount administered should be less than the cerebrospinal fluid removed. The serum should be given warmed to the body temperature and by the gravity method. Two or three additional doses should be given after the disappearance of the cocci from the cerebrospinal fluid in order to safeguard against relapse.

As regards the route of administration, the intrathecal route is the best, but in predominantly bacteraemic cases intramuscular injections of the serum may also be given in addition to the intrathecal injection. The intracisternal route is recommended in cases of sub-arachnoid block and is widely practised in the United States. It should not be undertaken by persons who have not had previous practice on cadavers.

Anti-anthrax serum. Anthrax is primarily a disease of animals and man is attacked only when engaged in an occupation which brings him in contact with such infected animals or their products. Of the three clinical forms of the disease the cutaneous type is the only one in which the administration of an antiserum is of some benefit. Although many different types of sera have been prepared and used from time to time, Selazo's serum, which is perhaps the earliest preparation (1895), is the best.

Selazo's serum is given in doses of 30 to 40 c.cm. subcutaneously followed by a similar dose after 24 hours if the local lesion or the general state of the patient does not improve. In severe cases 10 c.cm. should be given intravenously and repeated after 2 or 3 hours. In addition subcutaneous doses should be given as well. It should be noted that

the best results are obtained by the administrations of the serum at the earliest possible moment.

Antityphoid serum. Although attempts have been made to use antityphoid serum in the prophylaxis and cure of typhoid fever, the results have been very contradictory and the value of such treatment is extremely doubtful. Gross (1930) prepared a necrotizing toxin from *Bact. typhosum* and he used this toxin for immunizing horses. The antitoxin so prepared is capable of producing both a prophylactic and curative action in mice. Besides the antitoxin it also contains agglutinins, complement fixing and bactericidal bodies. Reports on the clinical use of such a serum will be of great interest.

Antivenin. This is an antitoxic serum against snake venom and considering the large number of deaths occurring in India from snake bite, it should be one of the most useful antisera. Unfortunately however there are so many practical difficulties in the preparation and use of this serum that it has not so far been very successful. For details see chapter on snake venom.

Antistaphylococcus serum. That the pathogenic staphylococci, particularly *Staphylococcus aureus*, may be associated with a toxin has been known for a long time, but the disaster at Bundaberg in Queensland in 1928, when 12 children died within 2 hours after being inoculated with a diphtheria prophylactic consisting of toxin-antitoxin mixture, which had become contaminated with staphylococci, led to renewed interest in the subject. Parker (1924) and Parker, Hopkins and Gunther (1926) recommended the growth of the staphylococci in an atmosphere containing 10 per cent. carbon dioxide and the use of Difco peptone instead of Witte's peptone for the production of the specific toxin in the culture medium. Gross (1929) has prepared an antiserum, which is both antitoxic and antibacterial. He prepared this by simultaneous injection of the toxic filtrate subcutaneously and heat-killed coccal suspensions intravenously. He titrates this antitoxin against a dry standard toxin by skin tests on rabbits. The standard toxin is taken to be that amount which when injected intracutaneously into rabbits causes a well-marked necrosis of the skin within 24 hours.

Puerperal infections caused by the staphylococcus have been treated with large daily doses (100 c.cm.) of this serum in Germany. It should be used as a precautionary measure in cases of furuncles of the lip, carbuncles, puerperal infections. The use of staphylococcal toxoid in the treatment of furunculosis has already been discussed in the section on vaccine therapy.

Antigasgangrene serum. The importance of this condition in the infection of wounds was recognised in the last War. Wounds grossly contaminated with soil containing anaerobic and aerobic organisms are most likely to show signs of gas gangrene. Antiserum prepared

against *Cl. welchii*, *Cl. oedemattens* and *Cl. novyi*, which are the commonest infective agents in such wounds, was extensively tried both for treatment and prophylaxis and has been found to be of great value particularly in prophylaxis. Gas gangrene is not so commonly met with in civil practice but in the likelihood of a wound being infected with anærobic bacilli, a polyvalent antiserum should be injected as a prophylactic measure. The serum given intravenously and injected into the deep tissues near the wound has been found to give satisfactory results and as much as 1,000 c.cm. may be required. It is most important to treat the wound surgically in addition to the serum treatment.

This serum has also been used in acute abdominal conditions such as appendicitis and intestinal obstruction. Williams recommends administration of 80 c.cm. of the serum intramuscularly and an additional 40 c.cm. intravenously in very severe cases of intestinal obstruction. On subsequent days 40 to 80 c.cm. should be given intramuscularly until the distension has disappeared and the bowels are moving spontaneously and regularly. A prophylactic dose before operation is advisable. Its administration as an adjuvant to operative measures has proved to be of great benefit. It has also been used in the treatment and prophylaxis of puerperal sepsis due to infection with these pathogenic anærobic organisms. For such infections Wrigley recommends the use of 40 c.cm. of the concentrated specific serum for prophylactic purposes. Other conditions in which this serum has been found to be useful are perirectal abscess, gangrene of the lung and diabetic gangrene.

Antiviral Sera

Measles. The cause of this disease is a filtrable virus which is present in the blood and nasopharyngeal secretions during the acute stage of the disease. It has not been possible to obtain an antiserum by immunizing animals so that human convalescent serum is needed for prophylaxis. This serum has no curative value. There are two types of protection :—(a) Full but temporary protection ; (b) incomplete protection resulting in a mild attack of the disease. One attack of the disease confers a lasting immunity.

Full protection may be needed for children in a poor state of health, particularly those below three years, for children suffering from tuberculosis, rickets, diphtheria, whooping cough or scarlet fever if exposed to the risk of infection.

The effective dose for such a purpose depends on, (1) the age of the child; (2) the state of his health; and (3) the interval between the time of exposure to the infection and the time when the serum is given; this should not be more than five days. The average minimum dose is 10 c.cm. and the dose for children over three years of age is determined

by multiplying the age of the child by two and the result gives the number of c.cm. of serum to be administered. The duration of the protection so conferred depends on the time of its administration. If it is given before exposure the immunity lasts from 2 to 4 weeks, but if given early in the incubation period, some degree of active immunity may be superimposed upon the passive immunity and if this happens the patient will be protected for a few months.

Convalescent serum, normal adult human serum and whole adult blood are three different agents used for such protection. It is not always easy to obtain convalescent serum so that normal adult human serum from persons who had an attack of measles in their childhood may be used with the same result, but it has to be used in larger doses. The use of adult whole blood has the advantage that children can be injected with the blood from their parents when it will be unnecessary to perform a Wassermann test. The adequate dose of adult serum is 12 to 25 c.cm.; of the whole blood 25 to 50 c.cm. are needed to confer full protection.

Acute anterior poliomyelitis. Human sera from three sources are used:—(1) Convalescent serum; (2) serum from persons who had an attack previously even up to 10 or 20 years; (3) serum of normal adults with no history of having suffered from the disease. There is evidence to show that normal human serum contains immune bodies probably as a result of an acquired immunity due to sub-infective doses of the virus in childhood.

From 10 to 20 c.cm. is given at the earliest possible moment intrathecally, and this is followed immediately by a dose of from 40 to 200 c.cm. intravenously. The intrathecal dose may be repeated on two or three successive days, but there is no necessity for repeating the intravenous dose. There is no danger in injecting human serum intravenously, as it is rarely followed by unpleasant sequelæ. It is no use giving the serum after paralysis has set in.

Prophylactic inoculation can be done either by human antiviral serum or by immune serum from horses. Flexner and Stewart (1928) suggest a subcutaneous dose of 10 c.cm. for children and 20 c.cm. for adults repeated after 4 or 6 weeks if exposed to infection.

Chicken pox. Although a comparatively harmless disease, prophylactic measures are justified due to the long incubation period necessitating a prolonged quarantine. Convalescent serum has been used for this purpose.

Mumps. Convalescent serum has been used both for prophylaxis and alleviation of symptoms and complications of this disease. The results so far obtained are encouraging but not convincing.

Dengue. Convalescent serum has no protective action when given prophylactically or in the treatment of the disease.

BACTERIOPHAGE THERAPY

The discovery of bacteriophage is of comparatively recent date. Twort (1915) in a paper entitled "Investigation on the nature of ultra-microscopic viruses" first noted the existence of such an agent. d'Herelle, working at the Pasteur Institute, Paris, discovered a curious phenomenon in sterile filtrates of stools of patients suffering from the Shiga type of dysentery. The unique feature of this phenomenon, and one outside the realm of previous experience, was that the lysis produced by filtrates in cultures of this organism was transmissible in series *ad infinitum* without exhaustion of the lytic principle. This lytic principle was named *Bacteriophagium intestinale* or *Protobios bacteriophagus*. d'Herelle (1917) considered the bacteriophage to be a minute, ultra-microscopic, living organism, parasitic upon, and lytic towards bacteria and he has since done considerable amount of work in support of this theory.

Although bacteriophage, as we now know it, has been known for only 18 years, there are to be found indications of appreciations of its existence in the past. Most discoveries have their roots in the past. In certain parts of India the droppings of birds have been used for centuries past in the treatment of dysentery and other intestinal diseases; the use of cow-dung spread on the floors of kitchens as a purifying agent, was at one time, and still is, in many, if not all, parts of India, a common routine in the households. These practices were undoubtedly based on experience and clinical observations of many generations. The droppings of birds have been shown to contain very powerful bacteriophages against the organisms of dysentery, at times against the cholera vibrio, and even the typhoid group of organisms. The spreading of cow-dung to 'purify' the kitchen-floors, etc., although now shrouded in the rituals of religion, is an efficient, though undoubtedly a very primitive form of disseminating bacteriophage. The drinking of river waters, the administration of certain waters to the sick would also appear to be a method of bacteriophage prophylaxis and bacteriophage therapy.

Hankin (1896) drew attention to the purifying effects of the river water. He noted the bactericidal properties of the waters of the Jumna. At Agra, for instance, he found that the river water contained 100,000 bacteria per c.cm., whereas 10 miles further down there were only 100 per c.cm. This observation remained unexplained till the discovery of bacteriophage. Other workers also observed many peculiarities in cultures of intestinal organisms. Gildemeister (1917) observed the nibbled appearance and defective colonies of dysentery and coli organisms without recognising their abnormality. This we now know as a phenomenon of bacteriophage.

Nature of bacteriophage. Opinions differ regarding the nature of bacteriophage. A controversy as to whether it is a living organism or a dead product of a living organism is still raging. If we consider the size of bacteriophage it will be appreciated how very difficult it is to settle the question of the nature of such an object. Bacteriophage is ultra-microscopic, *i.e.*, not visible by the most powerful microscope. It has a dimension of 20 to 30 $\mu\mu$ *. Recent studies show that phages are composed of particles whose size is uniform for any phage, though varying from phage to phage. The smallest phage has a diameter of 8 to 12 $\mu\mu$, while that of the largest phage varies between 50 to 75 $\mu\mu$.

According to d'Herelle bacteriophage is an autonomous, living, strictly parasitic organism belonging to the group of filterable viruses, which multiplies at the expense of, and causes the dissolution of bacteria. He is of opinion that there is but one bacteriophage with an infinite number of strains. To this parasite he has given the name of *Protophobos bacteriophagus*. Other workers do not believe that bacteriophage is a living ultramicroscopic organism. Many consider that bacteriophage is a ferment, either living or dead. Kabesima (1920) considers it to be a secretion from the intestinal glands that acts as a catalysator on the proferment contained in all bacteria and causes their digestion. Bail (1921) formulated the hypothesis that bacteriophage is a disintegration product of bacteria, probably derived from the chromosomes. Bordet and Ciuca (1921) consider that the phenomenon of bacteriophage is due to an inherited autolytic power on the part of bacteria. Hadley (1928) is of opinion that bacteriophage, as it occurs, is a definite stage in the life cycle of all bacteria or that it is an essential constituent accessory to the various stages. Otto and Munter (1924) state that it is a ferment-like action of the colloidal particles of bacterial cytoplasm.

* $\mu\mu$ or millimicron— $1/1,000$ th μ , or $1/1,000,000$ mm.

Phenomenon of bacteriophagy: lysis and mutation of bacteria.

The phenomenon of bacterial lysis has been extensively studied in the case of cholera and plague. The stool of a patient recovering from cholera contains phage, and if a trace of such filtrated stool is introduced into a fairly turbid culture of cholera vibrios, this culture becomes perfectly clear after some time, all the vibrios being dissolved. Under the microscope this destruction of vibrios can be watched. It consists of swelling and spherulation of the organism, production of granules and finally disintegration of the bacteria. The clear liquid can again be inoculated into a fresh culture to obtain the same effect and the process can be repeated indefinitely. This illustrates the important characters of lysis of bacteria by bacteriophage, *i.e.*, its filterability, transmissibility and that it can be subcultured in series with living and growing bacteria.

The phenomenon of bacteriophage can be observed in young bouillon cultures of the cholera vibrio as well as in other media. In a solid medium and under suitable conditions there can be seen upon the surface growth of a certain number of more or less circular areas generally called plaques, within which no growth has taken place. These are the colonies of bacteriophage. They vary in size from that of a pin head up to 4 to 5 mm.; small-sized phages give rise to large plaques and large-sized phages to small plaques.

If the plates with their areas of plaques are further incubated, it is found that, after a certain time, small colonies develop in these areas. A similar phenomenon in the form of return of turbidity is observed in bouillon cultures rendered clear by phage. The explanation is that after a certain time secondary colonies of bacterial cultures develop which consist of strains of bacteria resistant to the action of phage.

The adaptation of bacteriophage to produce intense lytic action on bacteria is important. It is more commonly adapted to one particular species of organism though its affinity for more than one species has been observed. Therapeutically active phage should, therefore, be highly lytic towards the specific organism. This adaptation of phage towards the specific organism can be brought about by growing it with specific bacterial species till the lytic power is developed. If, however, the phage is originally weak the lytic power can be augmented by repeated passage with a substrate organism. This lytic power of phage is not unlimited, and the importance of the adaptation of bacteriophage towards bacteria can be realised from the fact that on it depends to a great extent the success or failure of the struggle that is going on between bacteria and the defensive mechanism of the host.

Bacteriophage is one of the most powerful agents in bringing about changes in the morphology, cultural and serological reactions of bacteria. These reactions are known as mutation and dissociation of bacteria and consist in alteration of motility and morphology, capsule

formation, proteolytic power, agglutinability, virulence, formation of filter-passing forms, etc. The main results of such changes are development of resistance to lysis, greater viability, and increased susceptibility to phagocytosis. According to d'Herelle, these alterations are brought on by bacteriophage, and are evidence of a reaction on the part of bacteria towards a pathogenic organism, which in this case is bacteriophage itself.

The modification of bacteria in this way may be so complete that secondary cultures from the original strain may be morphologically quite different. D'Herelle described extremely resistant and stable forms of cocci obtained by repeated transfers of young secondary cultures of dysentery, typhoid, paratyphoid, coli and cholera organisms. Hoder (1925) stated that there is definite possibility of transition of *Bact. coli* to paratyphoid-like forms. Doorenbos (1932) claimed the El Tor vibrio as a phage-modified form of cholera vibrio.

The conversion of non-haemolytic organisms to haemolytic forms, of agglutinating to non-agglutinating species by the action of bacteriophage, has been described by many workers. In the case of cholera, Pasricha and his co-workers (1931) state that there is some bacteriophage as well as serological relationship between the true cholera vibrio and the cholera-like forms. Many of these latter forms are considered to be only mutation forms of the true cholera vibrio and play a great part in the incidence of cholera. Morrison (1931), on the other hand, concludes from his experiments that the alterations in the cholera vibrio are due probably to the occurrence of bacterial contamination.

Specificity and types of bacteriophage. Burnett (1933) stated that bacteriophages are independent micro-organisms and differ widely in site and activity. d'Herelle considers that there is only one species of phage but that it is capable of a high degree of adaptation to pathogenic organisms. There may be races of phage with a specific affinity for a certain strain or a species of bacteria to the exclusion of all other strains of the same species, which procedure has been regarded as a valuable aid to the diagnosis of bacterial species.

Several types of bacteriophage have been recognised especially with regard to cholera. This is dependent upon the fact that with the development of a resistant series of bacteria on culture, a bacteriophage may be discovered which lyses these resistant strains. In this way, so far as cholera is concerned, several types of cholera phage have been recognised. In India, Asheshov called his types A, B and C; Pasricha and his co-workers (1932) have added types D, E and F to these already known ones.

Preparation of bacteriophage. The technique of bacteriophage study and the general principles of bacteriophagy are so highly specialised that they involve special methods and what first appears to be a highly complicated technique. In reality it is perhaps one of the simplest

techniques in the whole subject of bacteriology. It must be remembered that we are dealing with an organism which is so small in size that it passes dense filters which hold back all microscopically visible forms of life. This extreme minuteness of the bacteriophage corpuscle is of very definite advantage because it makes it possible for the bacteriophage to be separated from all visible forms of life by the simple process of filtration. Bacteriophage also possesses an additional property which is of extreme value in its preparation and study. It can only grow and multiply at the expense of living susceptible bacteria. Its food is the living bacteria and so far it has not been possible to devise any method for its propagation except on living material and those of its host.

Technique of filtration. This varies according to the nature of the fluid required to be filtered. It is generally done in the following way. Sterilised funnels with filter paper are filled with kieselguhr suspension. This leaves a very thin coating of kieselguhr on the filter paper, which retains most of the bacteria, giving an almost crystal clear solution. This clear filtrate is now filtered through porcelain candles under vacuum of 15 inches.

Isolation of bacteriophage. In order to isolate bacteriophage from stools, about 5 c.cm. of the stool, if liquid, or a small portion if solid, is mixed in a small flask containing broth (papain broth or any other liquid medium). If it is thought that the bacteriophage present is minimal, a few c.cm. of young peptone water culture of the organism, against which bacteriophage is sought, are added. The addition of fresh culture is made with the object of giving the bacteriophage present the opportunity to develop and thus to be more readily found.

Isolation of bacteriophage from water is done by following the same procedure. Large amounts of water may be necessary, and often preliminary filtration is required before the addition of 'enriching organisms.'

Rôle of bacteriophage. The phenomenon of death, recovery and immunity from diseases has been explained on the basis of development or absence of bacteriophage. d'Herelle believes that such a phenomenon is not dependent upon immunity, as is generally understood, but on the occurrence of bacteriophage. In the case of cholera, cases which do not develop bacteriophage die; cases with feeble bacteriophage, which disappears, also die; cases with strong bacteriophage at the outset recover promptly; cases with weak bacteriophage, which increases in potency, recover with some delay and the ups and downs in the clinical progress of the case represent the behaviour of

the bacteriophage. Bacteriophage by infecting bacteria, causes destruction and death of bacteria and is the direct agency of recovery of disease in man. By an indirect process it brings about a state of acquired immunity. Bacteriophage, by causing a solution of the bacteria, presents the bacteria in a condition to serve as ideal antigens. The lysates contain the lysed bodies of bacteria and induce in the body the mobilisation of the defensive forces.

If, however, the bacteriophage is not powerful enough or conditions are not suitable for the total destruction of the invading bacteria, then one of the two things may occur:—

(1) The bacteria may overcome the infection by bacteriophage, and develop an immunity against that particular bacteriophage and persist as avirulent saprophytes; in this condition they are entirely non-pathogenic. The question now arises whether these bacteria under any circumstances again become virulent and pathogenic. There is no direct evidence to either admit of this possibility or to define the conditions necessary for such changes to occur. It appears to be highly probable, however, that such changes do occur in nature and it is only rational to conceive that such changes should be the rule rather than the exception.

(2) The bacteria may not be able to completely rid themselves of the infection by bacteriophage, and although they develop an immunity against that particular phage, they lead a life in harmony with bacteriophage. There is a symbiosis between the causative organism and the bacteriophage and this results in attenuation of the virulence of the bacterium; such bacteria cause chronic disease. Acute diseases are due to young healthy disease-free or bacteriophage-free bacteria; chronic diseased conditions are caused by the diseased unhealthy phage-infected bacteria, which, in spite of their disability, yet retain sufficient invasive power to maintain a chronic diseased condition.

Such is the line of reasoning which has been advanced, but from the very nature and number of variable factors present, the proof of such conditions actually occurring is not very

convincing. *Bact. typhosum* in its active pure stage causes typhoid fever provided certain conditions exist under which it can exert its full invasive power, but *Bact. typhosum* contaminated with bacteriophage—the organism of the ‘carrier state’—may only cause a chronic infection such as cholecystitis. *V. cholerae*, when pure and healthy, kills a high percentage of those infected, but when parasitised by bacteriophage, the mortality rate is low or may cause very mild symptoms. *Past. pestis* kills rats when free, but when diseased it causes only a chronic form of plague. The theory of bacteriophage can even embrace a complete and consistent theory of acquired immunity, but these ideas should not be stretched too far in our present stage of knowledge.

Bacteriophage in prophylaxis of disease. d’Herelle has shown a very definite relationship between the occurrence of bacteriophage in nature and the incidence of certain intestinal diseases, particularly cholera and dysentery. At the beginning of the cholera season very few samples of waters collected from the river Hooghly and from the tanks in Calcutta show the presence of cholera phage. During the height of the cholera season the incidence of bacteriophage in nature increases till about 40 to 50 per cent. of the samples of water show the presence of powerful cholera phages. At the end of an epidemic, the whole bacteriological picture changes; instead of the cholera vibrio possessing typical characters which may be likened to a well-organised army, there are towards the end of an epidemic, a heterogeneous group of organisms varying in their power, some difficult to recognise as vibrios, which are like the ragged disorganised members of a worn out army. All the factors that bring about this change are not known, but it is known that this enemy of man, the cholera vibrio, has been in conflict, amongst other forces, with bacteriophage which has played an important part in disorganising the invasion of the cholera vibrio. The course of a cholera epidemic is a struggle between vibrio and phage for dominance, and the ups and downs of an epidemic are the visible effects of that stupendous invisible battle that takes place in nature. The battle-ground is the intestine of man.

This concept of prophylaxis and immunity is so radically opposed to our ideas of epidemiology that at first it is difficult to appreciate its importance. It must be realised now that there exist in nature two very distinct forces—one, certain bacteria which are harmful to man and that the source of these harmful bacteria in the majority of instances is man himself; the other, another living force, which because it is harmful to bacteria is of distinct value to man. This second force is, as it were, provided by nature to maintain a state of equilibrium between man and his bacterial enemies. It is a police force provided by nature to guard mankind in times of stress. If conditions are favourable this force of bacteriophage multiplies so readily and becomes so powerful that it brings to an end the supremacy of the bacteria.

These theories raise very important points both in the prophylaxis and treatment of epidemic diseases. From this point of view the question arises whether the propagation of bacteriophage is advisable. To do this are we to allow the unhampered dissemination of natural bacteriophages which would necessitate the cessation of all public health activities, and to rely entirely on the results of the natural adjustment between the bacteria and the bacteriophage? These last factors may be so variable that it would not be justifiable to allow the cessation of the stringent sanitary measures. The bacteriophage as it exists in nature has had centuries of free play, unhampered by any sanitary measures, and we still have big epidemics of intestinal diseases. Secondly, the bacteriophages as they exist in nature may be supplemented by specially trained and highly virulent bacteriophages. In this way it may be possible to marshal together the natural enemies of bacteria, and harness nature for the benefit of mankind. This certainly must appeal to everyone as the most rational point of view. Experiments in the laboratory and trials with bacteriophage in the field, both as a prophylactic and therapeutic agent, have been undertaken by several workers, and although bacteriophage prophylaxis and therapy have made great progress, the subject is still under trial and no definite conclusions can be drawn from the experiments reported so far.

One thing can be definitely stated and that is that the results of the trials so far are not against bacteriophage; there is evidence highly suggestive that bacteriophage is of value. Though great hopes were raised at first of the therapeutic value of bacteriophage, the results so far have not fulfilled these hopes. Great things are still expected from bacteriophage which on purely theoretical grounds possesses all the attributes of an ideal internal antiseptic. It has no action whatsoever on any living tissue, kills the invading organism rapidly and increases in amount as it does so. The conditions within the body may and do modify the effectiveness of its attack, but it is hard to believe that an active phage can be entirely without effect on the course of an infection by a sensitive organism.

Therapeutic uses. As early as 1921 bacillary dysentery was treated with administration of bacteriophage and since that time various results were obtained with this form of therapy.

According to d'Herelle, in the bacteriophage there is a natural therapeutic agent which is of value in the cure of disease as well as in prophylaxis. It has already been pointed out that an active specific phage possesses all the attributes of an antiseptic, and it kills the specific organism against which it is employed and increases in amount during this process. From this point of view it was considered a valuable therapeutic agent in bacillary dysentery, cholera and various other bacterial diseases. Unfortunately the success with bacteriophage treatment is not uniform and its usefulness has been disputed by many workers. It is said that the action of bacteriophage is brought about by purely chemical means and that the effects produced are nothing but a reaction due to the introduction of a foreign protein. Topley, Wilson and Lewis (1925) used bacteriophage in strictly controlled experiments with mouse typhoid infection. Their observations were that the presence of bacteriophage does not prevent the spread of infection, check an epidemic when it has once started, or appreciably reduce the mortality. They further found that there is no evidence of development of immediate immunity either from infection or ingestion of bacteriophage.

The majority of those who are however willing to accept d'Herelle's hypothesis are of opinion that bacteriophage is a living ultramicroscopic virus which is capable of being a parasite on bacteria and which is said to dissolve and destroy them through the agency of a ferment it secretes. In addition to its direct action on bacteria, bacteriophage may also exert an indirect action by increasing the phagocytic power of the leucocytes, the explanation being that the lysins secreted by bacteriophage are really of the nature of opsonins. The cultures of bacteria lysed by bacteriophage have been considered to act as highly effective vaccines because of their capacity to produce antibodies possessing a far more protective power than the antibodies obtained from ordinary bacterial vaccine. The bacterial split products obtained under the action of bacteriophage are in a physical or chemical state highly suitable to induce a strong and durable immunity so that this immunity adds indirectly to the value of bacteriophage as a therapeutic agent.

According to d'Herelle many of the unsuccessful results of bacteriophage therapy are due to the inadequate technique in the preparation of phage. Only the virulent type of bacteriophage is effective and hence it is either therapeutically effective or without effect.

The rôle of bacteriophage as a therapeutic agent is as yet complex. Satisfactory results can only be obtained by following certain procedures. It is to be understood that there is an essential difference in principle between the treatment of acute and chronic infectious diseases with bacteriophage. In cases of acute disease a powerful bacteriophage must be brought into contact with the pathogenic bacteria before they have had opportunity to produce sufficient lesions to cause death. Chronic cases possess a different aspect altogether from the point of view of bacteriophage treatment. In this condition a state of partial symbiosis exists between the infecting bacteria and the phage and in order to bring about a full therapeutic effect a race of bacteriophage has to be employed which is virulent for the bacteria.

The mode of administration and dosage of bacteriophage requires some consideration. Bacteriophage, to be of any value, should be administered as early in the course of the disease as possible. Bacteriophage must come into direct contact with the invading organism and hence in intestinal disorders it should be given by the mouth. In cases of infection of the urogenital tract bacteriophage has to be introduced directly into the bladder, localised infections of subcutaneous or deep tissues require the direct application of bacteriophage in the infected focus. With regard to dosage and frequency of treatment it may be stated that the amount of bacteriophage to be given depends upon the virulence of the bacteriophage employed. This is due to the fact that bacteriophage in the presence of susceptible organisms perpetuates itself and the amount administered does not determine the amount that will ultimately develop. In case of acute infections a few administrations may be sufficient while in chronic types of infection bacteriophage therapy may have to be continued over a long period.

Bacillary dysentery. The treatment of bacillary dysentery with bacteriophage is now widely recognised. Fletcher tried bacteriophage in 22 cases of Flexner infection, but the treatment was a failure, while in the Shiga type of infection the bacilli disappeared from the stool on the second day of the disease. Morison, however, obtained encouraging results in an epidemic of dysentery; 70 cases were treated with 2 c.cm. of bacteriophage three times daily and of these three died and the rest were all cured. The author has treated a large number of cases of both acute and chronic dysentery with bacteriophage with indefinite results. In a few cases the effect produced appeared to be marvellous, but in the majority of cases no improvement could be detected. The results of trials by various observers, however, appear to indicate that bacteriophage therapy in bacillary dysentery is worthy of further trial.

Cholera. Bacteriophage therapy in cholera has been advocated. In this connection it is worthy of note that the therapeutic phage employed in the treatment of cholera must be virulent. The existence of a case with virulent bacteriophage should therefore draw special attention. Along with this must be considered the vibrios; some may yield to a phage of higher virulence while others may lead to actual diminution in the virulence of the bacteriophage. In order to obviate this difficulty Asheshov recommends a method of keeping therapeutic phage virulent by repeated cultivation on a freshly isolated vibrio.

The results published by d'Herelle and others (1930) who investigated the problem of bacteriophage treatment on behalf of the Government of India, appear to be striking enough. In a total of 198 cases, 74 received bacteriophage treatment, of whom only 6 died; while in a series of 124 cases not receiving the phage treatment the mortality rate was 78 per cent. Morison and Vardon (1929) used a combined dysentery-cholera bacteriophage in two epidemics of cholera in Assam. A mortality of 75.8 per cent. resulted in cases having no bacteriophage, while the death rate was 29.0 per cent. in cases receiving bacteriophage treatment. They mostly employed 2 c.cm. of phage four times daily by the mouth and serious cases received 2 c.cm. along with hypertonic saline. Souchard (1930) on the other hand failed to obtain any benefit and in his series a mortality of 24 out of 27 resulted.

The therapeutic efficacy of bacteriophage in epidemic cholera as investigated by Morison (1932) is worthy of note. Two areas were selected, keeping one as control. In the test area receiving bacteriophage, the district remained free from cholera for five successive epidemic seasons, while in the control area there was one outbreak each season. The account given by Asheshov, Khan and Lahiri (1931) gives a very promising picture of the bacteriophage treatment of cholera, coupled with simultaneous administration of hypertonic saline. Their method of treatment lies in giving bacteriophage in one drachm doses every 30 minutes, the bacteriophage being given undiluted and sipped directly from the bottle. Two bottles of bacteriophage, each containing 50 c.cm., should be finished in 16 hours, during the following 24 to 48 hours another bottle may be taken. They also employed bacteriophage by the intravenous route, in doses of 5 c.cm. considerably diluted, in order to prevent the occurrence of anaphylactic shock.

Although there is some evidence to show that bacteriophage may be of definite therapeutic value, further systematic work is necessary before any definite opinion can be given regarding its efficacy in the treatment of cholera in epidemic form.

Enteric fever. Contrary to the favourable results obtained with bacteriophage therapy in the infections of the intestinal canal such as dysentery and cholera, its efficacy in enteric fever is doubtful. Some clinicians have reported excellent results. Strains of phage virulent to the organism *in vitro* under laboratory conditions have been obtained, but these may be entirely ineffective in actual treatment of the disease. There are, however, occasional favourable reports with bacteriophage treatment. The usual dosage in such cases is 2 c.cm. of the phage three times daily for four to five days. Intravenous injections of the phage have been resorted to, to lower the temperature and hasten recovery. In view of these results and of the diverse reports that have been published regarding bacteriophage therapy in typhoid and paratyphoid

fevers, the question of application of bacteriophage in the treatment still remains unsettled.

Plague. The treatment of plague by bacteriophage has not as yet been carried out on a large scale and its value is therefore still undetermined. d'Herelle reported successful treatment of four cases of bubonic plague and stated that this method of treatment offers much promise. Couvy and his co-workers (1930 and 1932) reported favourable results of treatment in severe cases of human plague with a polyvalent phage. They affirmed the perfect safety of treatment of plague with bacteriophage even by intravenous injection. Two hours after injection of the phage, *Past. pestis* are found to be in a state of lysis. Pons (1932) reports very interesting results with bacteriophage therapy. He states that bacteriophage when given subcutaneously is rapidly generalised and produces lysis of the plague bacilli in 24 hours. As long as the lytic principles are present, blood or the aspirated material from the bubo remains sterile. Other workers have failed to substantiate these claims. Compton (1928) tried bacteriophage in experimental plague of animals but obtained indifferent results. Pirie (1929) stated that there is little evidence in support of either therapeutic or prophylactic value of bacteriophage in plague. Naidu and Avari (1932) had little success with a strain of powerful bacteriophage in human or in animal plague. According to d'Herelle, however, the bacteriophage therapy may constitute the specific treatment for plague; 1 to 2 c.cm. of virulent bacteriophage culture should be injected as soon as possible. The differences in results, according to him, may be attributed to the fact that in many cases the bacteriophages employed were several weeks old, and were not, therefore, sufficiently potent to deal with specific types of *Past. pestis* which may be extraordinarily virulent. As it is not possible to identify the organismal type before use of a phage in plague, all workers now emphasize the necessity of using a polyvalent potent phage. Very encouraging results, with comparatively little reaction, have been obtained in plague with a polyvalent bacteriophage. In bubonic plague the bacteriophage is administered subcutaneously and into the bubo in doses of 2 to 3 c.cm. on the first day and again on the second day; on the third day it is given subcutaneously. In septicæmic plague 3 c.cm. of phage have been given in the course of 24 hours, repeated if necessary within three days. Recent experiments (unpublished) on mice carried out in the Haffkine's Institute have shown that bacteriophage has no protective or curative effect in infection with *Past. pestis*.

Pyogenic Infections. Certain favourable results are also reported in localised septic conditions due to staphylococci and streptococci. Furunculosis, carbuncles, abscesses, osteomyelitis and miscellaneous infections have been treated by this method. The usual procedure of application of bacteriophage in these cases is to administer it by subcutaneous injection, although a few investigators have combined such injections
